Now consider the systolic blood pressures at baseline, the start of the trial, among patients enrolled in a clinical trial for an antihypertensive drug. The protocol will specify some severity of hypertension for included patients, but there will still be variability among patients at baseline. We use the language of probability to create a model for such variability. Suppose the average baseline blood pressure among all eligible patients is $\mu$ and the variance is $\sigma^2$. It is often the case that a collection of blood pressures follows a bell-shaped curve that we might characterize as a normal probability distribution. We then say the output—baseline blood pressure $B$—is predicted from the inputs—$\mu$ and $\sigma^2$—according to the Normal probability model:

$$B \sim N(\mu, \sigma^2) \tag{2}$$

In (2), $B$ is called a random variable; $\mu$ and $\sigma^2$ are both considered parameters. Note that to represent a random variable as an output from its distributional model we use ~ instead of =.

Imagine observing steady-state concentrations by taking blood samples and assaying them. Even if model (1) is reasonable, and even if we know CL as well as $R$, our observed concentration will probably not exactly equal $C_{ss}$ because of measurement error and because of physiological fluctuations that render the model incomplete. We account for this discrepancy by introducing a new variable, usually denoted $\varepsilon$, called the residual error. It is modeled as a random variable, analogous to the baseline blood pressures (2), and we often use the same Normal probability model. We usually assume a mean of zero for residual errors, so the only input is the variance, $\sigma^2$. We then expand (1) to

$$C_{ss} = \frac{R}{\mathrm{CL}} + \varepsilon \tag{3}$$

$$\varepsilon \sim N(0, \sigma^2) \tag{4}$$

Note that in (3) $\varepsilon$ plays the role of an input, but in (4) it plays the role of an output. Chaining models together in this way gives modeling great power while maintaining conceptual simplicity.

Suppose we administer a single intravenous bolus dose $D$ of a drug at time 0, and suppose the systemic circulation behaves as if it is a single well-mixed compartment. Then the systemic concentration $C$ of drug may be predicted as a function of the inputs dose ($D$), time post dose ($t$), clearance (CL), and compartmental volume ($V$) as

$$C(t) = D \exp\left(\frac{-\mathrm{CL}\, t}{V}\right) \tag{5}$$

Models with time as one of the inputs play a very important role in clinical trials (and throughout science), so it is common to highlight the input time by using it as an arugment in a representation of the output as a function, as $C(t)$ in (5).

The one-comparment model (5) is somewhat special because we can write the dependence of concentration on time algebraically. Frequently, models with time as input can only be expressed by describing how the rate of change of the output

depends on time and other inputs, that is, as a differential equation. A differential equation corresponding to (5) is

$$\frac{dC}{dt} = -\left(\frac{\mathrm{CL}}{V}\right)C \qquad C(0) = D \tag{6}$$

The algebraic representation (5) is the solution to the differential equation (6). But often no algebraic solution can be found, and we must solve the differential equation numerically, which takes us to simulation.

### 1.2 What Is Simulation?

Simulation is the act of computing values of the output for given values of the input. In (1), if we plug in values for $R$ and CL and compute the resulting value of $C_{ss}$, we have accomplished a very simple simulation.

Usually, however, simulation refers to repeating such calculations many times for different values of the inputs to see how changes in the inputs translate into changes in the outputs. The three most common situations are:

1. One of the inputs is time, and the computations are done to see how the output evolves as time progresses.
2. One or more of the inputs is a random variable, and the computations are done to see how the output varies due to the random process(es) represented by the random variable(s).
3. Both 1 and 2 together.

### 1.3 Model Building

Models seldom spring fully formed from the heads of modelers, at least if "fully formed" includes specification of the values of the model's parameters. Usually, the parameters must be estimated by fitting the model to data. Often the structure of the model (e.g., algebraic functions, differential equations, or probability distribution) and the inputs that best predict the outputs are determined partly if not wholly by fitting different models to the data and choosing the one that seems best, a process called model building.

Fitting the model to data means selecting parameter values of the model to minimize some measure of discrepancy or maximize some measure of similarity between observed values of the output variable (the data) and predictions of the output variable from the model. The sum of squared differences between data and predictions is a measure of discrepancy; minimizing it yields a least-squares fit. A common similarity measure is the likelihood, which, as its name implies, quantifies how probable the observed data are according to the model; maximizing it yields a maximum-likelihood fit.

The more complex the model the better the fit in terms of least squares or likelihood. To decide when to stop building, called model selection, criteria may be used that penalize models for being too complex, both for the aesthetic appeal of parsimony and because theory shows that these criteria effectively home in on the best model. Two such criteria are the Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) [2].

## 1.4 Bayesian Methods

In the Bayesian approach to modeling, parameters are considered random variables not unknown constants. A parameter's probablity distribution represents our uncertainty regarding its value. To learn is to reduce that uncertainty, corresponding to a reduction in the variance of the parameter's probability distribution. At the start of a new learning step, the probability distribution is called the prior. When we acquire new data and thereby learn something about the parameter, the updated probability distribution is called the posterior. This process of updating our knowledge, called Bayesian inference, is accomplished via Bayes rule, a mathematical formula. Berry [3] provides an introduction to Bayesian methods and their application in clinical trials.

## 1.5 What Lies Ahead

The remainder of this chapter will describe types of M&S used in clinical drug development and types of clinical trials that strongly depend on M&S. Each section will begin with a statement of purpose for the type of M&S covered or for the use of M&S in the clinical trial.

The sections will frequently cross reference one another. Curly braces { } will denote section number cross references, whereas square brackets [ ] will denote bibliographical citations and parentheses ( ) will denote equation numbers.

Although the chapter's parts must be sequentially ordered in a print medium such as this, there is no perfect sequencing of the material. Figure 1 displays one possible configuration of the dependencies among the sections.

***FIGURE 1*** *Dependencies among chapter sections.*

The heart of the chapter is {2.4}, which covers dose–exposure–response (DER) modeling, the fundamental clinical characterization of how a drug works and how M&S helps determine what dose to give to which patients. {1.1}–{2.3} provide the fundamentals of M&S needed to understand how DER models are built and used. {2.5}–{2.6} introduce exciting new areas of biological modeling that support DER modeling with mechanistic underpinnings. {2.7} describes methods for characterizing higher level disease progression. Within the process of drug development, an important application of models is to support decision making; {2.8}–{2.9} cover that. Finally {3} showcases five types of clinical trials whose design and interpretation benefit from M&S; they are presented roughly in the order they might appear in a drug development program.

## 2 TYPES OF MODELING AND SIMULATION

### 2.1 Regression Models

**Purpose:** *To infer how one variable may be predicted empirically from one or more others using independent observations of those variables in a sample of subjects.*

One variable, such as blood pressure (BP) at the end of a hypertensive trial, is the output, called the response; and one or more others, such as baseline blood pressure, treatment, dose, age, and sex, are inputs, called predictors. The goal of relating the response to the predictors may be learning—for example, to devise a rule to predict future observations of the response—or confirming—for example, to test if one or more of the predictors, such as treatment, is statistically significant. The model is fitted to data comprising one record per subject, each record containing observations of the response and the predictors, with records from different subjects considered independent.

Instead of being derived from any scientific theory, the form of a regression model is selected as a compromise between mathematical convenience and the empirical representation of the data's shape. Often a linear model (7) suffices because relationships tend to be approximately linear over limited ranges of the data.

Simple linear regression has one continuous response, for example, BP, that depends on a continuous predictor, for example, dose, and residual error:

$$\mathrm{BP}_i = \beta_0 + \beta_1 \,\mathrm{dose}_i + \varepsilon_i \tag{7}$$

$$\varepsilon_i \sim N\left(0, \sigma^2\right) \tag{8}$$

where $\beta_0$, $\beta_1$, and $\sigma^2$ are parameters that are estimated by fitting the model to data and where the subscript $i$ indexes the data, that is, here the subjects. Presumably, if the drug were an antihypertensive, $\beta_1 < 0$.

The adjective "linear" refers to the linearity of (7) with respect to the parameters $\beta_0$ and $\beta_1$, not dose. If in (7) dose were replaced by, for example, the logarithm of dose, it would still be a linear model even though a plot of $\beta_0 + \beta_1 \log(\mathrm{dose})$ versus dose would be curved.

If there are several predictors, such a model becomes a multiple regression model.

Nonlinear regression is when some parameters appear nonlinearly, such as

$$\mathrm{BP}_i = \beta_0 + \frac{\beta_1 \,\mathrm{dose}_i}{\beta_2 + \mathrm{dose}_i} + \varepsilon_i \tag{9}$$

Suppose we create a new response variable, $Y$, by considering only whether BP dropped by 3 mmHg or not, for which we assign $Y = 1$ or 0, respectively. Logistic regression is where the logit transformation of the probability that $Y = 1$, say $p$, is modeled linearly as

$$\mathrm{logit}(p) = \log\left[\frac{p}{(1-p)}\right] = \beta_0 + \beta_1 \,\mathrm{dose} \tag{10}$$

Logistic regression is an example of a broader class of models called generalized linear models [4], where some function of the mean of the response is related linearly to the predictors.

A clinical outcome may be the time to some event, such as death. Regression models for such a response time are a major component of survival analysis. The chance of the event occurring in the next instant of time, given that it has not happened yet, is called the hazard. In the Cox proportional hazards model, the logarithm of the hazard is related linearly to the predictors.

Many statistics textbooks cover regression modeling. See [5] for a nontechnical introduction or [6] for a technical one.

### 2.2 Longitudinal Models

**Purpose:** *To infer how one variable may be predicted empirically from one or more others using observations measured at more than one time per subject in a sample of subjects.*

Whereas regression models {2.1} are appropriate when subjects independently contribute one observation each, longitudinal models describe multiple observations collected over time for each subject. The several observations of the same individual tend to be correlated, which must be accounted for by the model. This additional complication buys, for confirming purposes, additional precision and power, and, for learning purposes, additional insight into how the response evolves as conditions change.

Regression models generalize to longitudinal models in two ways: marginal models and mixed-effect models.

The focus of a marginal model is to predict the population's average response, generally for confirming purposes. As in generalized linear models {2.1}, some transformation of the average response is assumed to admit a linear structure in the predictors. The correlation structure is handled somewhat empirically using methods that are known to be robust with sufficiently large samples; see [7].

Marginal models have two main limitations. First, they require that all subjects have the same number of observations under the same design. Second, they generally are not informative about individual responses.

Mixed-effect models (MEMs) overcome these limitations. An MEM is constructed hierarchically, by chaining models together as described in {1.1}, starting from a model for the response of an individual. The parameters of the individuals' separate models are themselves outputs of regression-type models. This accounts for the necessary correlation structure of the data and allows the models to be fitted to data even where subjects have different numbers of observations at different times.

Let us consider an MEM generalizing (7–8) to describe a study where each subject receives successively higher doses at each of which BP is measured. Let $\mathrm{BP}_{ij}$ and $\mathrm{dose}_{ij}$ be the $j$th observed BP and dose for the $i$th subject. The MEM is

$$\mathrm{BP}_{ij} = b_{0i} + b_{1i}\,\mathrm{dose}_{ij} + \varepsilon_{ij} \tag{11}$$

$$b_{0i} = \beta_0 + \eta_{0i} \qquad b_{1i} = \beta_1 + \eta_{1i} \tag{12}$$

$$\eta_{0i} \sim N(0, \omega_0^2) \qquad \eta_{1i} \sim N(0, \omega_1^2) \qquad \mathrm{corr}(\eta_{0i}, \eta_{1i}) = \rho \tag{13}$$

$$\varepsilon_{ij} \sim N(0, \sigma^2) \tag{14}$$

Each subject has his or her own intercept and slope $b_{0i}$ and $b_{1i}$. These inputs to model (11) are outputs of the models (12). The random variables $\eta_{0i}$ and $\eta_{1i}$ are called random effects. They characterize the variation among subjects of the intercepts and slopes of the BP-vs.-dose relationships, and their presence accounts for the correlations among the several $\mathrm{BP}_{ij}$ values for the $i$th subject.

Suppose we believe that some of the variation in the dependence of BP on dose is due to age. We need only make age an input to the model for $b_1$ in (12):

$$b_{1i} = \beta_1 + \beta_2\,\mathrm{age}_i + \eta_{1i} \tag{15}$$

If any of the parameters in an MEM besides the variances appears nonlinearly, then the model is called a nonlinear MEM or NLMEM, which will figure prominently in {2.4}.

Longitudinal models for clinical trials are reviewed in [8]. See also [9].

## 2.3 Exploratory Modeling and Data Mining

**Purpose:** *In large data sets, to find patterns that can be used as hypotheses to guide further experimentation or as retrospective explanations of surprising signals.*

Exploratory modeling in clinical drug development has two main applications. The first is part of the guided knowledge generation that is common to all science, when some general goals of discovery are pursued in the hopes of generating hypotheses that might be confirmed with further experimentation. Examples are mining genomic data to find potential biomarkers, or mining clinical data to find possible new indications for marketed drugs.

An alternative setting occurs when a clinical trial produces some surprising signal, such as a worrisome toxicity. Sometimes called fire-fighting, exploratory modeling then seeks to propose a plausible story for the observed results. Such a story would ultimately require confirmation, and thus this second application is really one of

hypothesis generation like the first; but if strong enough, such modeling results might be proposed as tentatively confirmatory or at least satisfactorily descriptive for, say, a regulatory submission.

The steps of exploratory modeling are (a) defining the problem, (b) exploring the data with graphical, tabular, and numerical summaries, (c) building models, and (d) validating models.

In the first two steps, the scope of potential models is clarified by learning the structure and content of the data and identifying any important substructures such as grouping in study centers, or local laboratories with different reference ranges, or time profiles of observations.

The nomenclature of data mining, derived largely from computer science, often refers to modeling as the application of various algorithms. Commonly used algorighms are listed below. To link with our view of modeling {1.1}, for each algorithm we identify the kind of outputs. In every case, the inputs might be anything else in the database; finding the right inputs and their relationship with the outputs is the model building {1.3}.

*Classification Algorithms* The output is one or more discrete variables, such as responder versus nonresponder. Methods include logistic regression {2.1}, rule induction, decision trees, neural networks, *K*-nearest neighbors, and support vector machines.

*Regression Algorithms* The output is one or more continuous variables, such as blood pressure. Methods include linear regression {2.1}, regression trees, and neural networks.

*Segmentation Algorithms* The output is the assignment of a patient into one of several groups, or clusters, of patients that have similar properties. Methods include clustering techniques, neural networks, and visualization methods.

*Dependency Algorithms* The output is any variable in the data set, and often outputs are inputs for other relations in a chain or network that represents associations among different variables. Methods include correlation analysis, association rules, and Bayesian networks.

Finally, after a model is built, its prediction performance is evaluated. Cross-validation, bootstrapping, and bagging are the techniques usually used. Sensitivity, specificity, positive predictive value, negative predictive value, accuracy, and receiver operating characteristic (ROC) curve are the mostly used evaluation metrics. For a comprehensive introduction to these ideas and data mining generally, see [10].

### 2.4 Dose–Exposure–Response Modeling

A fundamental goal of drug development is to learn what dose of the drug to give to which patients. Most drugs reach their site of action via the systemic circulation, so drug concentrations in the blood or plasma are often more predictive of response than dose. Hence, one way of building a dose–response model is to concatenate a dose–exposure (or pharmacokinetic) model with an exposure–response (or pharmacokinetic/pharmacodynamic) model. But direct modeling of dose–response is also done. This section describes these various models.

### *Dose–Response Modeling*

**Purpose:** *To characterize the relationship between dose and any measurable response.*

Dose–response modeling is regression modeling {2.1} or longitudinal modeling {2.2} with dose as input and response as output. Examples are models (7–14). Responses may be biomarkers, clinical outcomes, adverse events, or even pharmacokinetics, although the latter merits separate consideration (see below). See {3.4} for use of such models in dose-finding trials.

### *Pharmacokinetic (PK) Modeling*

**Purpose:** *To describe measured drug concentrations as a function of dosing regimens and, usually, time.*

Pharmacokinetics is "what the body does to the drug," as in absorption, distribution, metabolism, and elimination (ADME). Systemic drug concententrations are measured in repeated blood (or plasma) samples over time after one or multiple doses administered to healthy volunteers or patients. PK models characterize such concentrations by mathematically quantifying the ADME processes as parameters such as clearance (the flow at which the drug leaves the body), volume of distribution (the apparent volume in which the drug is distributing), half-life (the rate at which the drug is declining, once transient events in the body have taken place, a parameter that combines influences of elimination and distribution). Examples of such models are (1, 3–6).

Models (5–6) are appropriate when the PK behaves as if drug distributes within a single, well-mixed compartment. Quite often, however, the PK data require assuming the drug distributes among multiple compartments; usually two or three are adequate to describe a PK profile. All such models are referred to as compartment models.

A comprehensive reference on PK models is [11].

Ultimately, the number of compartments in the body is (at least) the number of homogeneous tissues. This is recognized by physiologically based PK (PBPK) modeling, which, in the situation of transitioning from animal studies to first-study-in-man, attempts to predict the key human pharmacokinetic parameters in advance before doing the actual experiments {3.1}. A PBPK model is based on literature data in human and animal models about blood flows and sizes of respective organs, and on actual compound-specific PK data in animals (e.g., the rat, mouse, dog, and less often the monkey). For animal-to-human extrapolation, the approach is extremely resource intensive and problematic, despite recent advances. In rare situations, retrospective attempts to develop PBPK models have been largely successful, for instance, for well-known drugs (oncology, morphine) or in other applications, like extrapolations from adults to children [12].

Population PK is another extension of PK modeling; see discussion below for details.

Pharmacokinetics results provide instrumental knowledge along the development of a compound and are essential for the drug submission dossier to help characterize the clinical pharmacology of the new chemical entity [13]. The classical method for data analysis initially avoids models and is therefore sometimes called "noncompartmental analysis." Metrics of exposure to the drug like $C_{max}$ (the

maximum concentration value) and AUC (the area under the measured concentration time points) are determined through simple calculations. This approach, combined with cross-over experiments assessed by analysis of variance, is extremely powerful for descriptive and comparative purposes (e.g., across formulations or dosing regimens).

Quite often, the exposure metrics $C_{max}$ and AUC are considered as outputs in dose–response models (see discussion above). A commonly used model is the so-called power model:

$$\mathrm{AUC} = \beta_0\ \mathrm{dose}^{\beta_1} \tag{16}$$

Of interest is whether or not $\beta_1 = 1$, in which case the PK is said to be dose proportional or linear. Testing whether $\beta_1 = 1$ is a confirming role for (16).

### *Pharmacokinetic/Pharmacodynamic (PK/PD) Modeling*

**Purpose:** *To characterize the mutual variation of drug concentrations and biomarkers or clinical responses to the drug.*

Pharmacodynamics is "what the drug does to the body." PD data comprises observations of a marker of drug effect in a subject, be it a systemic marker (e.g., a hormone or a pathway intermediate), a diagnostic assessment [e.g., a QT interval within the electrocardiogram (ECG)], a surrogate marker [e.g., HbA1c for diabetes or CD4 counts for human immunodeficiency virus (HIV)], or a clinical outcome (e.g., fractures in osteoporosis, death in oncology). Usually, the observations are repeated over time, or, for single events such as death, the time to event is relevant.

A very simple class of PK/PD models, commonly used for clinical outcomes in chronic diseases, uses the same empirical forms as dose–response models (see discussion above) but replaces the input dose with a summary measure of systemic exposure such as AUC.

The objective of PK/PD modeling is often to describe temporal delays of the PD response relative to the PK. A classical type of PK/PD modeling for this purpose is the effect-compartment model, when the drug exhibits its effect in a compartment that is not in rapid equilibrium with the systemic circulation [14]. Such a compartment may represent a real physiological space, such as the brain for anesthetics, or it may be empirically imputed solely to account for the observed delay. The drug concentration in such a compartment is an output of the PK part of the model and an input for the effect of the drug on the PD. In some cases, when the distribution to the site of action is extremely slow, the maximal effect can be achieved late after the administration of the drug, when the systemic concentrations are no longer detectable (have reached levels below the limit of assay quantification).

Another more physiological approach for accounting for delays between the time course of the drug effect relative to drug concentration is the turnover model (initially introduced as the "indirect-response model") [15]. Under normal physiological conditions, the rate of production, $k_{in}$, of the marker of drug effect is equal to the rate of elimination, $k_{out}$; "nothing happens"—the level of the marker remains constant at $k_{in}/k_{out}$. Depending on the compound and the marker, the drug effect is described as a stimulation or inhibition of the rate of production or of the rate of elimination. For instance, a single turnover model is adequate to describe, across a broad range of bisphosphonate doses, the kinetics of selected markers of bone

degradation which are inhibited by 0–80% even in healthy subjects. These markers are fast, reacting over hours/days. Bone mineral density is a slow bone marker, where changes are detectable over months/years.

It is important that the PD assessment is part of the causal chain linking the dose of drug to the ultimate clinical effect (e.g., reduction of fracture in case of a drug for osteoporosis, diminishing the risk of heart failure for a cardiovascular drug). Biomarkers are important tools to make drug development more efficient. Reacting more quickly to therapeutic interventions than clinical responses, sometimes even in healthy subjects, they may be signals to guide rapid and inexpensive decision making. The number and type of links in the causal chain will vary; for example, a biomarker may be a parallel process to the clinical effect (as shown in Fig. 2) or it may be directly in the causal chain. Nonetheless, the biomarker should clearly indicate that the drug has bound to the intended target.

In the effect-compartment model and in the turnover model, concentration serves as the stimulus to effect. In contrast, there are situations where PK and PD are intimately linked and cannot be separated, for example, monoclonal antibody kinetics [16], where the PD, the interaction of the drug with its receptor, plays an important role in the actual disposition and elimination of the drug, the PK. With such target-mediated drug disposition, further complexities arise; for example, the system may become nonlinear, with overproportional increase in AUC with dose. PK/PD models are necessary; noncompartmental approaches for PK analysis are largely insufficient.

Further mechanism-based PK/PD models have been reviewed recently [17]. These authors highlight that the principles are well known and illustrate a large amount of experience with these models in a wide variety of therapeutic areas. Much of this experience has accumulated presently in academic settings. However, experience within the pharmaceutical industry is increasing dramatically as the potential of the approaches reaches the attention of senior management and regulators.

In early-phase drug development, PK and PK/PD models are often used to predict the concentration (and response) after multiple dosing based on the first human trial after single-dose administration. Such models may be used in clinical trial simulation {2.8} to help in planning future studies, such as proof-of-concept studies {3.3}.

Since the uncertainty under such circumstances is great, one cannot expect a model to be always right, even if it is based on the most accurate quantitative data and knowledge available at this particular point. Learning in the form of ongoing revision to the model ought to occur all along the development of the compound and should incorporate insights from the development of similar pharmacological entities or different compounds addressing the same therapeutic indication.

***FIGURE 2*** *Causal chain.*

In terms of regulatory submission, when a model is used for extrapolation, it must be validated beforehand or agreed upon with the regulators that the approach taken is convincing [18].

As an integrative tool later in development, population PK/PD modeling is more and more used for dose–exposure–response assessment [19]; see discussion below.

### *Population PK Modeling*

**Purpose:** *To explain and predict how systemic drug exposure varies among subjects.*

Population pharmacokinetics (PopPK) originated as an attempt to infer the patterns of PK response within a patient population from sparse PK data collected under routine clinical care [20]. Nonlinear mixed-effect modeling {2.2} was employed, according to which the parameters of compartmental PK models are themselves considered outputs of models where patient covariates (and random effects) comprise inputs. For example, clearance might depend on body size, age, and the presence of some concomitant therapy that induces a drug–drug interaction.

PopPK has evolved into a widely used tool in clinical drug development for characterizing the variability of PK in patient populations by means of nonlinear mixed-effect models [21, 22].

PopPK is valuable when "a reasonable a priori expectation exists that intersubject kinetic variation may warrant altered dosing for some subgroups in the target population" [23]. It can be used strategically to help assess a need for altered dosing, as in ethnic bridging [24]. It is also useful whenever PK understanding is needed but only sparse PK data can be collected, for example, pediatric trials [25]. Regulators frequently request a PopPK analysis as part of a submission dossier, and many drug development scientists believe that a PopPK characterization of variability is an essential component of a development program.

The steps of using PopPK for clinical trials are design, data collection, model building, model validation, and model application.

The design goal for PopPK is usually to extract useful PK information from few blood samples per patient. Optimal design methods have been implemented in software for such purposes [26].

Data collection can be problematic because the clinical sites are not always used to it. Care must be taken that dates and times of dosing and blood sampling are accurately recorded because errors in that data can lead to biased and imprecise estimates of the model's important PK parameters.

Building the submodels that describe how the compartmental PK parameters depend on covariates is an intensively data-driven task. Optimal strategies for this step are the subject of much current research [27].

Model validation is demonstrating that the model is credible for its intended purpose. If the only purpose is quantification and explanation of variability, then validation might consist of checking stability of the parameter estimates when refitting the model to random subsets of the data [28]. Ever more frequently, concentration outputs from PopPK models are used as inputs into models for clinical responses as part of integrated dose–exposure–response models (see next section) and for clinical trial simulation {2.8}. To be used for such a purpose, the model should be validated by demonstrating that its predictions are consistent with observed data

(predictive checking [29]), preferably new data that was not used as part of the model building (external validation [30]).

#### *Integrated Dose–Exposure–Response Modeling*

**Purpose:** *To comprehensively describe relationships among dose, exposure, and clinical response (efficacy and safety), often by pooling data from several clinical studies.*

The clinical response (effectiveness, undesirable effects) to a specific dose of a drug varies from patient to patient. With an integrative dose–exposure–response (IDER) model, one tries to understand which factors are responsible for individually differing responses. This information is important for the safe and effective use of a drug in individual patients. For example, it can help to specify an appropriate individualized starting dose, or the best way to adjust doses for individual patients [31].

The IDER analysis is typically done in two steps: First, the relationship between dose and drug concentration in blood (exposure) is described, and factors responsible for variations in exposure are identified (such as body weight or renal function); a PopPK analysis (see above) can provide this information. Second, the PK/PD relationship between drug concentration in blood and clinical response is investigated, and factors responsible for individual differences (such as gender or ethnicity) are identified. The PK and PK/PD models are cumulatively learned throughout the drug development process. Both mechanistic models (e.g., pathway models {2.5} or physiological models {2.6}) and empirical models (e.g., regression models {2.1} or longitudinal models {2.2}) are used for the development of the IDER relationships.

An IDER model can have a powerful impact in getting the drug approved and providing guidance on dosing. An example is the development of Certican (everolimus) in combination with Neoral (cyclosporine) for prophylaxis of acute organ rejection in renal transplant recipients. Studies in about 1200 patients showed good efficacy but unsatisfactory renal function when everolimus was administered as 1.5 or 3.0 mg daily together with full dose cyclosporine [32, 33]. An IDER model [34] revealed that improved efficacy was associated with everolimus exposures above 3 ng/mL, but that efficacy did not vary with observed cyclosporine exposures. On the other hand, better renal function was associated with lower cyclosporine exposures, whereas renal function did not vary with observed everolimus exposures. The IDER model thus suggested that therapeutic drug monitoring (TDM) should be used for everolimus to ensure that everolimus exposure is above 3 ng/mL in each patient, and that cyclosporine exposure should be individually reduced using TDM. This regimen was then prospectively tested in an additional study with about 250 patients that confirmed the predicted good efficacy and renal function [35, 36].

### 2.5 Pathways Modeling

**Purpose:** *To describe and quantify the dynamic behavior of biological signaling pathways.*

As discussed in {2.4}, clinical response to a given drug varies from patient to patient. This variability can be due to routinely collected demographic factors such as gender and race, but it can also be due to different protein and gene expression

levels, as well as mutations in relevant biological entities, such as the drug target or the drug metabolizing enzymes.

Mathematical models of signaling pathways elucidate the dynamical behavior of such relevant biological entities. In terms of target discovery and validation, such models may suggest what are the optimal ways that the system can be manipulated by drugs [37]. In targeted therapies used in oncology, such models can help elucidate possible combinations of drugs that would together achieve efficacy without interfering with the physiological function of the drugs' targets in normal tissue, thus limiting toxicity [38, 39]. In combination with molecular dynamics simulations, such models can address the role that a mutation in the drug target has in the overall clinical efficacy seen with a drug [40]. Schoeberl et al. [41] have used mathematical modeling to show that different protein expression levels from different cell lines and tissues can lead to largely different behavior of the same signaling network and thus helped to reconcile seemingly contradictory literature results.

Signaling pathways are usually modeled by a set of differential equations {1.1}, where the state variables are proteins or protein complexes within the signaling pathway. The kinetic parameters in the system include the Michaelis–Menten constant, turnover numbers, and rate constants of association and dissociation [42].

Development of highly predictive pathway models is difficult because such models require (1) complete characterization of the molecular interactions in the pathway and (2) numerical values for the parameters associated with the model equations. Parameter values are often determined via numerical optimization against experimentally measured quantities (model fitting, {1.3}). This, in turn, creates an additional complexity for models of realistic size since the number of the unknown parameters is too large as compared to the available experimental data [37]. Sensitivity analysis can determine the dominant parameters, which helps both by pointing to data that can best inform and constrain the model, as well as by suggesting possible biomarkers [43]. In addition, specialized techniques such as extended metabolic control analysis [44], determining the components that control the dynamics of signaling pathways, facilitate the extraction of the relevant pathway modules to be included in a larger disease model {2.7} for clinical development.

## 2.6 Physiological Modeling

**Purpose:** *To describe mathematical models of tissues and organs and outline possible utility in clinical drug development.*

Mathematical models of human physiology have been of interest for a long time [45]. The IUPS Physiome project (http://www.physiome.org.nz) represents a worldwide public domain to build a computational framework and quantitative understanding of human physiology and pathophysiology. As new data accumulates, these models have become increasingly more sophisticated and biologically plausible. Organs that have been described by such mathematical models include kidney [46], respiratory tract [47], heart [48], and even the whole human physiology [49]. Because constructing these models is complex, data intensive, and computationally expensive, such modeling efforts have been largely the subject of academic research with somewhat limited applications to human health. However, the situation appears to be changing with the accumulation of data, government funding, and establishment of consortia and collaborative efforts that pool data across different organizations.

One example for a tissue-level model that is being used to guide clinical decision making is that of cardiac electrophysiology. The last decade has been marked by the withdrawal of several medicines whose use in patients has been associated with the development of torsade de pointe (TdP), a potentially fatal polymorphic tachycardia [50]. Regulatory guidelines [51] propose the prolongation of the QT interval on the electrocardiogram as a biomarker for torsadogenic risk of a given compound. However, TdP is triggered by a dynamic combination of multiple factors, and so, in order to reduce the number of false positives and false negatives, pharmaceutical companies are looking into combining the strengths of different methodologies (both experiemental and modeling) to make the best informed decision. A detailed description of the cardiac system in humans allows inclusion of experimental data on the effects of different drugs in a relatively simple manner [52] and prediction of the effect of the molecules both in reference to healthy subjects as well as high-risk individuals. It is worthwhile to note that as the models become more predictive and computation becomes cheaper, such prospective simulations can be used routinely in the drug development process and can serve as data integration tools.

## 2.7 Disease Progression Modeling

**Purpose:** *To improve the assessment and predictability of a drug's impact on a disease by distinguishing drug-specific properties from disease-specific properties.*

Many chronic diseases that are targets of drug development, such as Alzheimer's, diabetes, and osteoporosis, are degenerative. The durations of clinical trials may not be insignificant on the time scales of disease progression. So disease progression is a source of variability, accounting for which can improve the detection of drug effect. On the other hand, clinical trials are almost always short relative to the expected duration of a drug's use by a chronic-disease patient. So a reliable forecast of a drug's long-term impact is important for developers, prescribers, patients, and payors.

Disease progression models first quantify the evolving status of a disease absent a drug and then characterize alterations induced by the drug. This hierarchical approach facilitates clarity, extrapolation to different dose regimens, and comparison of different drugs.

Although models for different diseases might be expected to have little in common, certain simple model forms have been found practical as well as conceptually enlightening. Chan and Holford [53, 54] considered the constant progression model,

$$\frac{dS}{dt} = \alpha \qquad S(t) = S_0 \tag{17}$$

where $S(t)$ is the disease status at time $t$, $S_0$ is the initial status, and $\alpha$ is the rate of disease progression. They cited use of such a model for Alzheimer's, Parkinson's, chronic obstructive pulmonary disease (COPD), and diabetic nephropathy.

A drug may alter $S(t)$ by affecting $S_0$, $\alpha$, or both. A drug effect on $S_0$ is considered a symptomatic effect; if drug treatment stops, $S(t)$ reverts to its original trajectory. A drug effect on $\alpha$ is considered a protective effect; if drug treatment stops, $S(t)$

***FIGURE 3*** *Untreated disease progression and symptomatic and protective drug effects.*

continues on a trajectory displaced from the original at the position where treatment stopped. See Figure 3.

Post et al. [55] introduced a class of models based on the disease process being a perturbation of a turnover model {2.4}. The disease alters $k_{in}$ or $k_{out}$ in a progressive way. Symptomatic drug effects add to or multiply the perturbed $k_{in}$ or $k_{out}$ without affecting the process of perturbation. Protective drug effects affect the process of perturbation directly. Models of this sort were applied to type 2 diabetes in [56].

## 2.8 Clinical Trial Simulation

**Purpose:** *To assess the expected performance of clinical trial designs and analysis methods.*

Clinical trials often have one or both of two objectives related to the two goals of drug development {1}: (i) learning—estimate some characteristic of the drug's behavior, such as the maximum tolerated dose; and (ii) confirming—test some hypothesis about the drug, such as whether the drug is superior to placebo. Modelers have long studied how different experimental designs, estimates, and tests affect the accuracy and precision of such inferences [57]. When their algebra and calculus are not powerful enough to quantify these properties, modelers resort to simulating {1.2} their experiments on the computer, for example, [58, 59].

Holford et al. [60] identified three broad classes of questions for which simulation experiments might be useful: (1) To investigate the properties of new model-based methods, such as nonlinear mixed-effect modeling for PopPK {2.4} [61]. (2) To study the properties of novel trial designs, such as concentration-controlled trials [62]. (3) Applications to specific clinical trials, for example, [63, 64]. For the latter, different designs can be input to the model and the best design selected for actual implementation based on comparison of the outputs. Simulating the different designs may

cost tens of dollars; actually conducting the trial may cost millions; the small investment of model-based forethought can have a big impact.

A trial simulation model may be thought of as one large model, the key input to which is the design of a clinical trial, and the key output of which is some performance measure of the trial. However, it is useful to consider component models. Commonly, these include an integrated dose–exposure–response (IDER) model {2.4}, a covariate distribution model, and a trial execution model [60].

The covariate distribution model describes the trial's target patient population in terms of the distribution of relevant covariates, such as the distribution of blood pressures in (2).

The trial execution model is a computer algorithm for simulating the trial. It generates simulated patients according to the covariate distribution model who experience outcomes according to the IDER model. The trial execution model may allow deviations from the trial protocol through noncompliance, missing observations, and the like. The trial's simulated data are statistically analyzed according to the protocol. This is done repeatedly for many simulated replications of the trial. Then the statistical outomes of all of the trials are summarized as a performance measure that addresses the question that motivated the simulation experiment.

An excellent compendium on clinical trial simulation is [65].

## 2.9 Decision Analysis

**Purpose:** *To help clinical teams create, compare, and evaluate strategies for clinical development, and to achieve clarity of action in choosing among strategies in the face of uncertainty.*

Modeling and simulation is a powerful tool for decision making due to its role in knowledge integration and its ability to quantify "what-if" scenarios via trial simulation {2.8}. Decision analysis is a structured process designed to facilitate effective communication between decision makers and a project team (including modelers and experts), driving toward clarity of action [66, 67]. Matheson and Matheson [68] characterize six components of a decision analysis: (1) framing, (2) strategy generation, (3) meaningful, reliable information, (4) clear values and trade-offs, (5) logically correct reasoning, and (6) commitment to action. Decision quality is achieved when further improvement in each component is not worth the additional time and resources that would be required. Each of these six components is now explained:

1. *Framing* consists of understanding the key questions. A decision hierarchy is developed to distinguish between those decisions already made, those decisions that are to be made now, and those that can be settled at a later time.
2. In *strategy generation*, creative doable strategies are assembled from different alternatives associated with the decisions to be made now.
3. *Meaningful, reliable information.* An integral feature of decision-analytic thinking is to accept the existence of uncertainties and to quantify them by means of probability distributions. Probabilities over clinical (and sometimes also market) possibilities may be developed via modeling from data, but also may be carefully assessed from experts in a manner designed to reduce various biases [69].

4. *Clear values and trade-offs* are selected to allow meaningful, quantitative comparisons of strategies. For-profit companies will typically be concerned with expected (i.e., probability averaged) net present (dollar) value. However, some useful proxies may also be evaluated, and then explicitly balanced against resources (i.e., cost and time). In early-phase "proof-of-concept" trials {3.3}, the proxy focus is typically the chance of a correct "go/no-go" after completion of the trial. In later phase (dose finding) trials {3.4}, the focus shifts toward the chance for correctly choosing the best dose regimen(s). For phase III trials, the focus is the chance of correctly confirming a compound's safety and efficacy, leading to successful registration. Beyond the clinical development of a single compound, larger decisions may be analyzed, such as allocation of resources between many development projects in a portfolio [70].
5. *Logically correct reasoning* proceeds comparing the performance of selected strategies against the chosen evaluation criteria. Typically, trial simulation and probabilistic (Bayesian) inference {1.4} must be used. Sensitivity analysis can also be performed and the value of information computed [67], allowing better focus on the most salient information.
6. *Commitment to action* among stakeholders is achieved by involving the right people in the above steps. This includes a planned sequence of opportunities for the decision maker to provide input into the frame, the strategies chosen for consideration, and the evaluation criteria.

Other authors might use the term "decision analysis" to refer to steps 3–5. Examples of such decision-theoretic M&S applied to clinical trial designs can be found in [71, 72]. However, the fuller decision analysis process that includes all of steps 1–6 often generates insights leading to improved strategies; teams who engage in such a systematic process frequently report that the open, guided discussion of assumptions, uncertainties, alternatives, and values along with emergent insights provide as much or more benefit compared with the mathematical model outputs.

## 3 M&S-BASED CLINICAL TRIALS

### 3.1 First-in-Man Studies

**Purpose of M&S:** *To estimate doses for first-in-man studies.*

A hallmark of a good development candidate is to have a high probability of surviving through the clinical proof-of-concept PoC study {3.3}, showing pharmacologically useful activity. To assess this one answers three questions: (1) Is the site of action exposed to sufficiently efficacious drug concentration for a suitable duration? (2) Do these concentrations have a suitable safety profile? (3) Can formulations that achieve these concentrations be developed? Several research and development functions generate data, each utilizing different methodologies. M&S should play a key role to fully integrate these data, anticipate doses likely to elicit pharmacological and adverse effects in humans, and then optimize the early clinical development program.

The dose for a first-in-man (FIM) study is generally determined by following international, public guidances of the International Conference on Harmonisation (ICH) E8 [73] and ICH M3 [74]. These provide the rationale for estimating a safe starting dose by specifying target organs, dose dependency, relationships to exposure, and potential reversibility in FIM trials. Further, ICH S6 [75] (for biologicals) defines the principle of relative safety exposure between test animals and humans. The no-observed-adverse-effect level (NOAEL) and the toxic dose in animals are the bases of anticipating the FIM dose, and uncertainty of estimation is accounted for by setting safety margins. The Food and Drug Administration (FDA) [76] gives guidance on the maximum recommended starting dose (MRSD) for FIM studies by $mg/m^2$-based scaling of Good Laboratory Practice (GLP) toxicology data with a typical 10-fold safety margin.

That said, the guidance [76] does not cover how to determine the pharmacologically active dose, that is, the lowest dose with the intended pharmacological activity, making MRSD essentially a safety secured dose. However, an MRSD far below the pharmacologically active dose requires a long dose escalation scheme, while an MRSD far exceeding the right dose range will not allow us to detect the complete dose–effect relationship [77]. In addtion, the guidance-compliant approach does not necessarily fully secure the safety, as highlighted in 2006 by TGN1412, a monoclonal antibody whose MRSD was calculated by conventional approaches with a 500-fold safety margin, but six healthy volunteers were seriously injured in the FIM study.

Collectively, a rational approach is demanded to efficiently anticipate FIM doses, in addtion to the guidances, following the core scientific principle that drug effects are a function of target exposure. A three-step process is practical to anticipate the human dose–response [78] (Fig. 4): (1) Experimentally, determine exposure–response relationship in preclinical (animal) studies. Blood (plasma) concentration is often considered as a surrogate to the target exposure, assuming drug distribution equilibirum between circulating blood and drug target. Summary measures such as AUC or $C_{max}$ {2.4} may be used if appropriate. (2) Adjust the exposure response curve from preclinical species to human. This will involve correcting for interspecies differences (e.g., known binding affinities to blood components and/or the drug target). (3) Convert the anticipated exposure–response to dose–response in humans using

***FIGURE 4*** *Anticipating the first-in-man dose.*

pharmacokinetic scaling, such as allometry [79] or physiologically based pharmacokinetic modeling {2.4} [80].

### 3.2 Oncology Phase I Studies

**Purpose of M&S:** *To optimally design and analyze first-in-man trials for oncology drugs.*

First-in-man trials for oncology trials differ from other therapeutic areas because oncology drugs often cannot be tested in healthy volunteers due to their toxicity at therapeutic doses. The typical design for such trials is therefore a dose escalation scheme in patients, with interim analysis and dose escalation/stopping decisions after each cohort. The primary endpoint is the occurrence of a dose-limiting toxicity (DLT), and the primary objective is the assessment of a maximally tolerated dose (MTD), corresponding to an acceptable target rate of DLTs. In order to optimally design such trials, the M&S challenge is to define decision rules for dose escalation and MTD selection (specifically, model-based rules), and to evaluate their operating characteristics through simulation.

Heuristic rules to decide upon dose escalation and MTD declaration have been proposed [81, 82], the most popular being the so-called "3+3" method, which bases decisions on whether to escalate, keep, or deescalate doses on how many DLTs are observed in the previous cohorts of size 3. Starting with the so-called continual reassessment method (CRM) [83], many model-based methods have been introduced, where decision rules and MTD selection are based on a model fitted to the available data. In its simplest form, where DLT is binary (i.e., occurrence or nonoccurrence), a model for DLT has the rate of DLTs as output and the dose as input along with parameters: rate of DLTs = $f$(dose, parameters). Due to the sparseness of the data (binary data from few patients), complicated models with many parameters cannot be fitted; thus, the proposed models typically have one or two parameters. An example is the two-parameter logistic function: logit(rate of DLTs) = $\alpha + \beta \log(\text{dose})$, where $\text{logit}(p) = p/(1-p)$ {2.1}. After each cohort, the model is fitted to the data, either through maximum likelihood {1.3} or using a Bayesian approach {1.4}. The latter has some distinct advantages since it allows to base decisions on posterior probabilities of the quantities of interest [84]. For example, one may want to specify the optimal target rate of DLTs to be in the range [0.25, 0.33]; anything beyond 0.33 would be deemed unacceptable toxicity. In a Bayesian framework, this is easily transformed to a decision rule, by choosing a dose maximizing the posterior probability of the rate of DLTs being in the interval [0.25, 0.33], while keeping the posterior probability that the rate of DLTs exceeds 0.33 below a threshold, for example, 0.05; this may be complemented with restrictions on how many dose levels to escalate.

The evaluation of operating characteristics is done through clinical trial simulation {2.8}. Generic features can be evaluated through the simulation of typical situations (see, e.g., [84]). However, specific trials with a unique set of prior assumptions and logistic restrictions will very often require specific simulation-based evaluation.

For a discussion of different approaches, with an emphasis on Bayesian methods, see [84] and the references given therein. For a nontechnical introduction see [85]. For references to extensions such as time-to-event and continuous outcomes, covari-

ates, combination trials, and combined safety–efficacy outcome, see references given in [84–87].

### 3.3 Proof-of-Concept Studies

**Purpose of M&S:** *To improve the information value of proof-of-concept trials with regard to efficacy and safety evaluation.*

Early development studies for establishing proof-of-concept (PoC) generally use small patient cohorts (typically between 10 and 20) observed for a relatively short period of time (several weeks) in a dose escalation design to evaluate early efficacy and safety signals. Cohorts are assigned, in sequence, to increasing doses until the maximum tolerated dose, generally determined in a previous study, is reached, or unacceptable safety is observed for a given cohort. A new cohort is only allowed to start once acceptable safety signals are verified for all previous doses. At the end of the study, one hopes either to determine a dose range for further exploration in phase IIb or to conclude that no PoC can be established based on the efficacy/safety trade-off.

Because of the small cohort sizes, only safety problems occurring in a relatively large percentage of patients can be reliably detected. Likewise, only relatively strong efficacy signals can be detected with reasonable statistical power using traditional pairwise hypothesis tests.

Safety and efficacy variables are often measured on a continuous scale and observed several times over the duration of the study. However, typically, the endpoints for the go/no-go decision are based on a single time point (e.g., change from baseline at end of study) and on dichotomized versions of the original variables to characterize responder/nonresponder behavior. An example of the latter is the transformation of continuous liver function test measurements [e.g., alanine aminotransferase (ALT) and aspartate aminotransferase (AST)] into binary indicators of exceeding three times the upper limit of normal. There are, therefore, two types of information loss often present in PoC studies: (1) not using of all available longitudinal measurements collected in the study and (2) the dichotomization of continuous endpoints.

Safety and efficacy signal detection can be made more efficient in a variety ways: by using information external to the trial and longitudinal modeling approaches {2.2} to exploit all available information. Furthermore, the utility of PoC studies within the drug development program can be enhanced by incorporating the information obtained in them directly into later phase trials. Bayesian modeling techniques {1.4} are particularly useful in implementing these different approaches.

The key idea is to use a Bayesian mixed-effect model (typically nonlinear) {2.2} to characterize the longitudinal dose–response behavior of efficacy and safety variables, measured on a change from baseline scale (e.g., log of measurement divided by baseline). Preclinical or other external data can be used in the elicitation of priors for the Bayesian model. The estimated model is then used to simulate longitudinal profiles of change from baseline for different doses, which are combined with a sample of baseline values, obtained from a database of previous trials with a similar population, to produce dose–response longitudinal profiles. Dichotomization and other transformations can be applied to the simulated profiles to evaluate efficacy and safety more efficiently compared to using a single dichotomized time point. An

additional benefit of the approach is that it allows the use of external information, frequently available in pharmaceutical companies.

### 3.4 MCP-Mod: Unified Strategy for Dose-Finding Studies

**Purpose of M&S:** *To combine multiple comparison procedures and modeling in dose finding.*

Understanding and adequately representing the dose response (DR) profile of a compound, for both efficacy and safety, is a fundamental objective of clinical drug development. Proper understanding of this relationship has both a confirming and a learning component: confirming whether there is an overall DR effect (proof-of-concept {3.3}); and if so learning which doses to select for further development (dose finding). Selecting too low a dose decreases the chance of showing efficacy in later studies, while selecting too high a dose may result in tolerability or safety problems.

The analysis of dose-finding studies can be classified into two major strategies: modeling [88,89] and multiple comparison procedures (MCP) [90,91]. Dose–response (DR) modeling {2.4} assumes a functional relationship between dose (taken as a quantitative factor) and the response, according to a prespecified parametric model (defined in the study protocol). While this provides flexibility in investigating the effect of doses not used in the actual study, the validity of its conclusions highly depends on the correct choice of the DR model, which is typically unknown.

A multiple comparison procedure regards dose as a qualitative factor and makes very few, if any, assumptions about the underlying DR model. It can either be used for detecting an overall dose signal by means of trend tests or for the estimation of target doses by stepwise testing strategies, while preserving the overall type I error rate at a prespecified level. Such procedures are relatively robust to the underlying DR shape but are not designed for extrapolation of information beyond the observed dose levels.

MCP-Mod is a hybrid methodology combining features of MCP and modeling to provide a flexible and principled approach for designing and analyzing dose-ranging studies. Its central idea is the use of a set of candidate DR models to cover the possible shapes anticipated for the DR relationship. MCP are applied to a set of test statistics, determined optimally for the models in the candidate set, to decide which shapes give statistically significant signals. If no candidate model is statistically significant, the procedure stops and declares that no DR relationship can be established from the observed data (i.e., no proof of concept). Otherwise, out of the statistically significant models a best model is selected for dose estimation in the last stage of the procedure. The selection of the dose estimation model can be based on the minimum $P$ value (of the candidate models) or some other relevant model selection criteria such as AIC or BIC {1.3}. The selected dose–response model is then employed to estimate target doses using inverse regression techniques [where the output (response) and input (dose) exchange roles] and possibly incorporating information on clinically relevant effects.

Simulation results suggest that MCP-Mod is as powerful as standard trend tests, while allowing more precise estimation of target doses than MCP, due to its modeling component [88, 92]. It is worth pointing out that this method can be seen as a

seamless design that combines proof of concept (phase Ib/IIa) with dose finding (phase IIb) into one single study.

### 3.5 Adaptive Trials

**Purpose of M&S:** *To determine the operating characteristics of an adaptive design, and ensure that the optimal design will be conducted.*

Adaptive designs are a relatively new type of clinical trial in which data from the trial can be used to modify some design aspect of the trial while the trial is still ongoing. This greater flexibility allows for design aspects to be modified in the case where some original trial design assumptions were incorrect, without having to wait for the conclusion of the trial. Such flexibility can save a considerable amount of development time for a novel drug. Adaptive trials can also combine what traditionally might be two separate studies into a single trial, thereby eliminating the time between the two trials. However, in order to design these trials, the decision process must be carefully thought out in advance and specified in the protocol. Often, clinical trial simulation {2.8} is the best way to understand and modify the operating characteristics of an adaptive trial.

Although there are many types of adaptation, one common type, sample size reestimation, is very appealing because often the parameters needed for sample size calculations are completely unknown at the beginning of the trial. Therefore, the idea is to try to estimate these needed parameters during the trial and modify the sample size accordingly. However, it has to be understood that at this interim time, the estimates for these parameters have considerable variability in them as well. Therefore, it might not be optimal to use such estimates directly, but instead use them to guide the calculation for the final sample size. A decision rule can be defined for how the sample size will be changed, and then computer simulation can be used to determine how the sample size would change under various scenarios.

Another type of adaptive design is a seamless adaptive design in which two trials are combined together. For example, a trial could be designed such that multiple doses are started in the beginning of the trial, and then the optimal dose is selected during an interim analysis. Additional patients would then only be randomized to the selected dosage group (and control), and all the data would be used at the conclusion of the trial to determine if the selected dose was indeed efficacious. If proper statistical testing procedures are in place at the end of the trial, then this type of design could cover objectives of both a phase II dose-finding study {3.4} and a confirmatory phase III trial.

For this type of seamless adaptive trial, simulation must also be used to determine the operating characteristics of the trial. For example, once a dose–response model {2.4} is assumed, and the dose selection algorithm is defined, the trial could be simulated to determine how often the selected dose would have a significant statistical test for efficacy at the conclusion of the trial (the statistical power for the trial). Another important characteristic of the trial that could be determined via simulation is the selection probabilities for each of the doses. Simulations should then be performed using different assumed dose responses, selection rules, and sample sizes to ensure that the trial has robust operating characteristics under many different scenarios.

For an introduction to adaptive trials, see [93].

## 4 DISCUSSION

This chapter introduces M&S in clinical drug development. Just a chapter cannot do the topic full justice, and indeed a thick book has recently been published that surveys the field [94]. The references herein provide some historical markers as well as some general introductions to specific methodologies. Readers interested in following trends would do well to monitor the journals *Clinical Pharmacology and Therapeutics, Journal of Pharmacokinetics and Pharmacodynamics, Statistics in Medicine*, and others cited in the references.

## 1 REASONS FOR MONITORING CLINICAL TRIAL DATA

Many traditional methods for the analysis of data assume that the data are all available contemporaneously. This reflects the setting of agricultural experimentation in which much of the methodology was developed, as data on crop yields from different fields are collected simultaneously after harvesting. In the majority of clinical trials, however, patients are recruited over a period of time, so that data accumulate gradually through the course of the trial, with data from some patients available prior to the recruitment of others. This accumulation of data makes possible the statistical analysis of some of the data collected before the trial is completed. Such analysis of data during the course of the trial is termed *monitoring*.

There are a number reasons why monitoring of clinical trial data might be considered desirable. The first is an ethical reason. In a randomized trial, randomization of subjects to receive one treatment or another is generally considered ethically acceptable provided there is *equipoise*, that is, an uncertainty as to which treatment is superior. If clear evidence was available that one treatment was of superior efficacy to the other, or that one treatment was less safe than the other, continued randomization would be considered unethical. In a single-arm trial, enrollment in the trial would be similarly considered unethical if the treatment being assessed clearly led to an unacceptable level of adverse events. Monitoring of efficacy and safety data allows the results of an ongoing trial to be regularly assessed and enables termination of the trial as soon as the results are sufficiently convincing that continued recruitment cannot be ethically defended.

The second reason for monitoring a clinical trial is administrative. As the trial progresses, it is desirable to ensure protocol compliance, check data collection procedures, and to monitor recruitment rates. The estimation of nuisance parameters (such as the unknown variance for normally distributed responses) used in power calculations can also be conducted to ensure that the trial will have a sufficient sample size before the close of recruitment.

The third reason for monitoring a clinical trial is economic. Clinical trials are expensive, and it is not in the interest of sponsors or patients to continue a trial once the results are clear. By monitoring the accumulating data, a clinical trial can be stopped as soon as sufficient data are available to justify a conclusion that an experimental treatment is superior or inferior to the control, or that the data clearly indicate that any difference is so small that continuation of the trial is futile.

In a blinded randomized trial we may consider data monitoring to be divided into three types: first, administrative monitoring of clinical trial conduct and monitoring of safety data with no monitoring of efficacy data; second, monitoring of efficacy data without unblinding of treatment allocation, for example, for the estimation of nuisance parameters; third, monitoring of efficacy data with treatment allocation unblinded to allow the estimation of the difference in efficacy between the treatments being compared. In the latter two instances, administrative and safety monitoring will most likely be conducted in addition. As will be discussed in Section 3, it is the third of these types of monitoring that presents the most ethical and statistical challenges. It is therefore on this type of monitoring that the majority of the chapter will be focused. Before moving on, however, the first two types of monitoring will be discussed briefly in the next section.

## 2 MONITORING OF CLINICAL TRIAL DATA WITHOUT UNBLINDING TREATMENT ALLOCATIONS

### 2.1 Administrative and Safety Data Monitoring

Monitoring of administrative data such as recruitment rates, accuracy of completion of record forms, treatment compliance, and data collection/transfer procedures is common in large clinical trials. The aim of such monitoring is to ensure that any problems in trial conduct or data collection are identified and rectified as soon as possible. Identification of incomplete record forms from a particular investigator could lead, for example, to collection of the missing data prior to the end of the trial, while observation of a lower than anticipated recruitment rate might justify the introduction of new centers in a multicenter trial. An example of a form to assess ongoing treatment compliance as part of a trial is given in Figure 1. Administrative monitoring of this kind is generally conducted without unblinding treatment allocation since treatment information is generally irrelevant. The risks of increased error rates or release of information about the performance of the study drugs that could lead to bias as discussed in Section 3 therefore do not arise from this sort of monitoring.

Many large trials also involve some monitoring of safety data. As discussed above, in a trial in which serious adverse events may be observed, this type of monitoring serves an important ethical function. In order to assess whether there is an excess number of adverse events in one treatment group relative to the other, it is necessary to unblind treatment allocation. In some cases, the two treatment groups are presented simply as groups A and B, without indicating which group is receiving the experimental treatment and which the control. However, it is generally easier to interpret adverse events in the light of the treatment administered, so that full unblinding is considered to be a better practice [1]. The unblinding of treatments introduces the risk of bias as discussed in Section 3. In order to minimize this risk, particularly in large clinical trials, the safety data may be reviewed by a *data and safety monitoring board* (DSMB) (sometimes alternatively called a *data monitoring committee*), so that only members of this committee need have access to the unblinded data. This committee decides on the basis of the unblinded data reviewed whether or not it is safe for the trial to continue and makes its recommendation to the *trial steering committee* responsible for the overall conduct of the trial. Further details of the role and function of DSMBs are given by Ellenberg et al. [2] and Whitehead [3]. Two example forms for monitoring adverse events are given in Figures 2 and 3. Figure 2 illustrates the categorizations to be used when determining adverse events and their attributability. Figure 3 shows how a case report form for serious adverse events might be structured.

As the purpose of safety monitoring is solely to recommend termination of the clinical trial if an experimental treatment is associated with too many adverse events, this type of monitoring cannot lead to a positive claim of effectiveness for the experimental treatment based on the monitored data. This means that, in contrast to the type of efficacy monitoring discussed in Section 3, there is no risk of a false-positive conclusion arising as a result of this monitoring; that is, the type I error rate cannot be increased. The special statistical methodology that is discussed in the rest of this chapter is therefore not required in this case.

## 2.2 Monitoring for Estimation of Nuisance Parameters and Sample-Size Reviews

Sample size calculations at the planning stage of a clinical trial often require the specification of values for unknown parameters other than the treatment effect of primary interest. These are often known as *nuisance parameters*. For example, if data are assumed to be normally distributed, the primary measure of relative treatment

**GUIDELINES FOR RECORDING OF ADVERSE EVENTS**

***FIGURE 2*** *Example categorizations for adverse event monitoring.*

efficacy will often be the difference in the mean response for the two treatments. Specification of the variance of the response, which is commonly assumed to be the same in the two groups, is, however, needed for calculation of the required sample size. A second example is for binary data, when the sample-size calculation depends on the average probability of success for the two groups. In practice, in such cases, the guess of the nuisance parameter required before the start of the trial may be inaccurate. This might lead to an inappropriate choice of sample size and to an underpowered or overpowered trial.

Gould and Shi [4] proposed, as a solution to this problem, the use of an analysis of the accumulating data part way through the trial to estimate the unknown nuisance parameter in what is usually termed a *sample-size review*. A review of the method and further advances in the methodology is given by Gould [5]. The required sample size for the trial can then be obtained based on this estimate of the nuisance parameter, and the sample size for the remainder of the trial adjusted accordingly. For example, suppose a trial with a normally distributed response was initially designed with a sample size of 100 patients. An analysis could be conducted when data were available from 50 patients to calculate the unknown common variance. At this point it might be revealed that the estimated variance based on the data was larger than the value anticipated when the trial was planned, so that the trial is likely to be underpowered. Based on the estimate from the data, the required sample size might be 120 patients rather than the initial 100 planned. The second stage of the trial could then recruit a total of 70 rather than 50 patients to give this total sample size. Simulation studies have shown that such an approach is effective in maintaining the power even if the initial guess of the unknown nuisance parameter is inaccurate.

In the case of normally distributed data, as in the illustration above, the nuisance parameter that is estimated at the sample size review is the common variance. The usual pooled variance estimate is given by

$$s^2 = \frac{1}{n_{E1} + n_{C1} - 2}\left[\sum_{j=1}^{n_{E1}} (x_{Ej} - \bar{x}_{E1})^2 + \sum_{j=1}^{n_{C1}} (x_{Cj} - \bar{x}_{C1})^2\right] \tag{1}$$

where $x_{E1}, \ldots, x_{En_{E1}}$, with mean $\bar{x}_{E1}$, are the $n_{E1}$ observations on the experimental arm and $x_{C1}, \ldots, x_{Cn_{C1}}$, with mean $\bar{x}_{C1}$, are the $n_{C1}$ observations on the placebo arm. The calculation of this estimate requires a knowledge of which patients are in which treatment group, so that the treatment allocation must be unblinded. As explained below, this is undesirable in clinical trial monitoring as it may lead to bias through the differential treatment and interpretation of further patients in the trial.

Expression (1) for $s^2$ can be rearranged to give

$$s^2 = \frac{1}{n_{E1} + n_{C1} - 2}\left[(n_{E1} + n_{C1} - 1)s_0^2 - \frac{n_{E1}n_{C1}}{n_{E1} + n_{C1}}(\bar{x}_{E1} - \bar{x}_{C1})^2\right] \tag{2}$$

where $s_0^2$ is the overall estimate of variance, which can be calculated without breaking the blind, given by

$$s_0^2 = \frac{1}{n_{E1} + n_{C1} - 1}\left[\sum_{j=1}^{n_{E1}} (x_{Ej} - \bar{x})^2 + \sum_{j=1}^{n_{C1}} (x_{Cj} - \bar{x})^2\right] \tag{3}$$

with $\bar{x}$ the overall mean.

This suggests a method for estimation of the standard deviation from blinded data. The first term in (2), depending on $s_0^2$, can be found from the unblinded data. An estimate of the standard deviation can thus be obtained from blinded data together with an estimate of $(\bar{x}_{E1} - \bar{x}_{C1})$, the treatment difference. Gould [5] suggests

using the treatment difference under which the power is calculated to give an estimate of the standard deviation on which a new sample size can be calculated. If we denote this difference by $\delta_R$, replacing $(\bar{x}_{E1} - \bar{x}_{C1})$ in (2) by $\delta_R$ gives an estimate of the variance of

$$\frac{1}{n_{E1} + n_{C1} - 2}\left[(n_{E1} + n_{C1} - 1)s_0^2 - \frac{n_{E1}n_{C1}}{n_{E1} + n_{C1}}\delta_R^2\right]. \tag{4}$$

If an estimate of the unknown variance is based on blinded data, the sample size reestimation procedure does not have any impact on the overall type I error rate, in contrast to the more general sequential monitoring that is discussed in the next section. The type I error rate may be inflated, however, if unblinded data are used to provide the variance estimate used for the calculation of the sample size for the second stage [6]. This gives further reason for the use of methods that do not require knowledge of treatment allocations.

## 3 DANGERS OF UNPLANNED CLINICAL TRIAL MONITORING

Although, for the reasons just described, monitoring of accumulating data in a clinical trial is very appealing, there are a number of dangers, particularly when considering treatment efficacy, to which careful attention should be given whenever data monitoring is considered.

The main danger is a statistical one: The conduct of multiple analyses can lead to difficulty in the interpretation of the results [7]. In particular, if significance tests comparing experimental and control treatments are performed more than once, with testing stopped as soon as a significant result is obtained, the type I error rate is inflated as explained below.

When a single significance test is conducted, it is performed in such a way that the probability of declaring the treatments to be different if in fact they are identical, that is, of making a type I error, is controlled, usually to be 5%. If the test is repeated at a number of analyses, with each test conducted at the 5% level and the procedure stopped as soon as a significant result is obtained, there is risk of a type I error at each of these analyses. The overall probability of such an error, the type I error rate, will thus be more than 5%. The effect of repeated looks conducted at the 5% level in the simplified setting of comparison of normal data with known variance was assessed by Armitage et al. [8]. They showed that in this setting while a single analysis has a type I error rate of 5% as planned, if two analyses are conducted, the overall type I error rate is increased to 8%, with this increasing to 14% if five analyses are conducted, and increasing further if the number of analyses is more than five.

The problem of type I error rate inflation means that monitoring of clinical trials cannot be conducted without the use of specialist statistical methodology to ensure the type I error rate is controlled at the nominal level. The remainder of this chapter gives descriptions and examples of such statistical methods, explaining how valid tests may be obtained. A clinical trial conducted using such methodology is called a *sequential clinical trial*, and the formal analysis of data part way through the trial is known as an *interim analysis*.

A further statistical problem, related to that of type I error inflation, is that of estimation at the end of a monitored clinical trial. Just as the type I error rate is inflated because the trial stops exactly when extreme results are obtained, so a conventional estimate obtained at the end of a sequential clinical trial will be biased because the trial stops exactly when positive results are seen at an interim analysis. Again, special statistical techniques are required to provide a valid analysis, as described below.

In addition to the statistical problems associated with the conduct of interim analyses, there are some practical problems that may make monitoring of efficacy data difficult or undesirable. In some trials the primary endpoint may be some measure, such as long-term survival, that is observed only after considerable follow-up. In this case, all patients may be treated before the primary endpoint data from even the first patients enrolled in the trial are observed. This means there is no possibility of stopping the trial as a result of interim analyses. Although there may be some advantage in monitoring the efficacy data even in this case, for example, to obtain the results of the trial more quickly, there is no potential saving in terms of trial length or sample size.

If the data observed early in a trial are not considered typical of all of the data that are likely to be observed, the results of an interim analysis may be misleading. Monitoring of efficacy data in this case is thus undesirable and should be avoided. An example might be a comparison of treatments for cancer when the primary efficacy endpoint is survival, and one treatment is expected to lead to excess early mortality, but to better long-term prognosis. If only early death data were available at an interim analysis, the long-term advantages of this treatment could be missed, and the trial halted erroneously.

The final danger associated with many data-monitoring strategies is the need to unblind the treatment allocation. If treated patients continue to be followed-up, there is a danger that knowing which treatment they are receiving may lead to a difference in the level of care for or interpretation of results from patients in the experimental treatment and control groups. This may give rise to bias in the treatment comparison. The release of interim results may also lead to reluctance among investigators to recruit patients, or reluctance among the patients themselves to consent to randomization, if there is some evidence of a treatment difference, so that equipoise is no longer considered to exist.

## 4 METHODOLOGY FOR SEQUENTIAL MONITORING OF UNBLINDED EFFICACY DATA

As described above, some clinical trial monitoring, such as monitoring of adverse events for safety, or the estimation of nuisance parameters from blinded data for sample-size review may be conducted with no risk of type I error rate inflation or effect on the final analysis. The monitoring of unblinded efficacy data, with the chance to stop the trial early if a large difference between the treatments is observed, does, however, lead to an increase in the type I error and bias in the analysis unless specific statistical methods are employed. The remainder of this chapter describes such methods and illustrates how valid monitoring of efficacy data can be conducted. Most of the statistical methodology in this area has been developed for clinical trials

in which two treatment groups, often corresponding to an experimental treatment and a control treatment, are compared. It is on this type of trial that the rest of the chapter will be specifically focused.

Whitehead [9] gives a list of the four key elements that must be considered in the design and conduct of a sequential clinical trial to assess treatment difference. These are a parameter giving some measure of the advantage of the experimental treatment over the control treatment; test statistics that give information on the size of this advantage on the basis of the data observed at an interim analysis and the amount of information about the treatment difference that is given by the observed data; a stopping rule that determines, on the basis of the observed test statistic, values at an interim analysis whether the trial should continue or should stop; and a final analysis method, valid for the stopping rule used, that enables a conclusion of whether or not the experimental treatment is superior to the control and provides a $p$ value and point estimate and confidence interval for the treatment difference at the end of the trial.

The four elements are now considered in detail. Specification of the first two, the treatment difference parameter and the test statistics, is required whether fixed sample size or sequential methods are employed, but is discussed here for completeness. The specification of the third, the stopping boundary, represents a solution to the problem of control of the type I error rate. A number of solutions to this problem have been proposed, leading to several different approaches to the way in which the stopping boundary is calculated. These are described below. Although the fourth element, the analysis, is very important in the interpretation of the results from the sequential trial, statistical methodology in this area has generally lagged behind that for the construction of stopping rules. In practice, the use of an appropriate final analysis has often been neglected, in part due to the lack of availability of suitable software. Methods for the valid analysis have been developed, however, and the analysis can now be conducted using commercially available software. The methods are described briefly below and the alternative computer programs are discussed in the next section.

### 4.1 Parameterization of Treatment Difference and Test Statistics

As in a fixed sample-size trial, the first stage in the design of a sequential clinical trial is the specification of some primary measure of treatment efficacy. This measure should be chosen on the basis of clinical relevance, ease and accuracy of measurement, and familiarity to clinicians. Following the definition of the primary endpoint, an associated parameter measuring the difference between the experimental and control treatments must be chosen. This will depend on the type of data collected on the primary endpoint, the interpretability of the parameter, for example, whether a difference or a ratio is more familiar, and the precision of the resulting analysis.

For example, if the primary response is a dichotomous variable such as whether a cancer patient is in remission or not after one year, the chance of being in remission in each group can be measured by the odds of remission, and the difference between the treatment groups can be measured by the ratio of the odds in the two groups, or more commonly the logarithm of this ratio, the *log-odds ratio*. If the primary response is a continuous measure such as weight loss, a difference in true unknown mean weight loss for the two groups would be of interest. If the primary

response is the time to some event, such as death, the difference between treatment groups might be measured by the ratio of the hazards in the two groups or the logarithm of this ratio.

At each interim analysis, some test statistic measuring the difference between the experimental and control treatments based on the observed data is calculated together with a test statistic measuring the amount of information given by the observed data at that interim analysis. Whitehead [10] and Jennison and Turnbull [11] suggest using a measure of difference known as the *efficient score* statistic and a measure of information called the *observed Fisher's information*, though other pairs of statistics may also be used, such as an estimate of the treatment effect and its standard error as suggested by Jennison and Turnbull [12] or a $p$ value for comparison of the treatments and the planned sample size, as is used in *repeated significance testing* described in the next paragraph and in the *adaptive design* approach described in more detail in the last section of this chapter.

### 4.2 Repeated Significance Testing

As discussed above, if a simple significance test comparing the experimental and control treatment groups is conducted repeatedly at the 5% level until a significant result is obtained, the overall type I error rate will be increased above 5%. Armitage et al. [8] showed how the actual error rate could be calculated when the number of repeated tests is specified. Similar calculations to those performed by Armitage et al. can be used to enable repeated significance testing with overall type I error rate controlled at the 5% level. By conducting each individual test at a more stringent level, the overall type I error rate is reduced, and so may be reduced to be 5% as desired. Numerical computation may be used to calculate the required error rate for each of the repeated tests to ensure that the overall level is 5%.

Pocock [13] proposed such a repeated significance testing approach, giving tables of the nominal type I level at which each test should be conducted to give an overall type I error rate of 5 or 1% for different numbers of tests. For example, to give an overall type I error rate of 5%, if two tests are performed each should be carried out at the 2.94% level, whereas if five tests are conducted, the nominal level for each should be 1.58%.

The repeated significance tests described by Pocock [13] are assumed to all be conducted at the same nominal level so that the same critical value is used for a standardized test statistic at each of the interim analyses. In general, there is no requirement that this should be so. If, say, five interim analyses are planned, it is possible to use different nominal levels for the five significance tests and control the overall type I error rate to be 5%. An alternative pattern of significance levels was proposed by O'Brien and Fleming [14]. They constructed the repeated significance tests in such a way that the level of evidence required to reject the null hypothesis that there is no difference between the two treatments at the earlier analyses is greater than that required to reject it at later analyses. In particular, the critical value for the $i$th interim analysis is chosen to be $k_1/\sqrt{i}$ for some constant $k_1$ chosen to maintain the overall type I error rate at the desired level. This choice of nominal levels, while maintaining the overall type I error rate, makes stopping at early interim analyses almost impossible, negating some of the advantages of sequential analysis. The Pocock [13] design, on the contrary, has been criticized, for example,

by Pocock and White [15], for leading to too high a chance of early stopping. Alternative approaches have been proposed [16], although the repeated significance testing approach has been largely superceded by the more flexible spending function approach described in the next section.

### 4.3 Spending Function Approach

A disadvantage of the repeated significance testing approach is that the number of interim analyses and the timing of these in terms of the amount of information available at each analysis need to be specified in advance in order to calculate the critical values required to control the overall error rate. Lan and DeMets [17] introduced a more flexible approach in which neither the timing nor the number of interim analyses need be given at the design stage.

Rather than specifying the critical values at a number of interim analyses, Lan and DeMets [17] proposed that the stopping rule should be given by a *spending function* that describes how the overall type I error rate, say 5%, is spent through the course of the trial. At the design stage, the maximum amount of information that will be attained if the trial does not stop early is calculated. At each interim analysis the level of information currently available is evaluated and the *information time* calculated to be the proportion of the maximum information available from the current data. The spending function gives, as a function of this information time, the amount of type I error that is to be spent, and the hypothesis test is conducted at such a level to ensure that the overall type I error spent up to and including this interim analysis is equal to this amount.

The spending function is thus an increasing function of the information time. It takes value 0 for information time 0, that is, at the start of the trial, and value equal to the overall type I error rate for information time 1, that is, at the end of the trial. It is common to denote the information time by $t$, and the spending function by $\alpha^*(t)$. Suppose that interim analyses are taken at information times $t_1, t_2, \ldots$. The critical values used for the hypothesis tests at each of the interim analyses are chosen so that the probability of stopping and rejecting the null hypothesis at any of the interim analyses up to and including the $i$th is equal to $\alpha^*(t_i)$ if the null hypothesis is really true. Equivalently, if the null hypothesis is true, the probability of stopping and rejecting the null hypothesis at the $i$th interim analysis given that the trial has not stopped at an earlier interim analysis is equal to $\alpha^*(t_i) - \alpha^*(t_{i-1})$. The critical values to give these stopping probabilities can be calculated using a recursive numerical integration technique similar to that used by Armitage et al. [8] to evaluate error rates for repeated significance tests. A similar technique enables calculation of the probability of stopping under a specified alternative hypothesis, and this allows the maximum information level to be chosen to give a test that satisfies some power requirement. Further details of the spending function approach and the computations required to calculate the critical values and sample size are given by Jennison and Turnbull [11].

As in the repeated significance testing approach, there is considerable flexibility regarding how likely the trial is to stop at the different interim analyses within the constraint that the overall type I error rate is controlled at the desired level. In the spending function approach this flexibility is expressed in the choice of the spending function, which may be any increasing function rising from 0 to the overall type I

error rate. A number of forms for spending functions have been proposed. Lan and DeMets [17] give spending functions to give approximations to the repeated significance testing procedures of Pocock [13] and O'Brien and Fleming [14], while Kim and DeMets [18] and Hwang et al. [19] suggest possible families of spending functions.

The flexibility of the sequential stopping boundaries in terms of the form of the spending function was utilized further by Kim and DeMets [18]. They showed how two different spending functions may be used to construct tests that have different properties for positive and negative treatment differences.

The sequential approach can be extended further to give tests that have different power to detect positive and negative treatment differences. A lower power is associated with a smaller sample size. Since the sample size is no longer fixed, but is now a random variable depending on the observed data, it is possible to stop the trial earlier for certain observed treatment differences than others. In particular, the stopping rule may not be symmetric, so that different decisions may be taken for positive and negative observed differences of the same magnitude. This is valuable, for example, in a clinical trial comparing an experimental treatment with a placebo. If the experimental treatment is superior to the placebo, we desire a high probability of rejecting the null hypothesis that there is no difference, and we are willing to randomize the large number of patients required to demonstrate this. If the experimental treatment is actually inferior to the placebo, demonstrating this is of less interest. It is sufficient to show that the experimental treatment is either the same or worse than the placebo and to continue to randomize patients to discover whether the disadvantage associated with the experimental treatment is significant or not is undesirable. Whitehead [10] calls asymmetric tests of this type tests with *power requirement I*, in contrast to the more usual symmetric tests, which he calls tests with *power requirement II*. Sequential procedures with power requirement type I can also be constructed using the spending function approach [20, 21].

### 4.4 Boundaries Approach

The repeated significance testing approach and the spending function approach provide a stopping rule. In each case, for each interim analysis conducted, a pair of critical values is obtained, and the trial is stopped if the test statistic lies outside of the interval defined by these two values. The critical values are said to form a *stopping boundary* and the set of intervals to form a *continuation region*. The observed values of the test statistic measuring the treatment difference at the interim analyses are said to form a *sample path*, which is compared with the stopping boundary to decide whether or not the trial should continue.

An alternative to the methods for construction of the stopping boundary described above is based on the abstract concept of continuous monitoring, in which it is imagined that the value of the test is observed at all times rather than just at the discrete times given by the interim analyses. In this case, a plot of the test statistic measuring the treatment difference against that measuring the amount of information available forms a continuous line. In the *boundaries approach*, this continuous line is compared with continuous stopping boundaries that are expressed as functions of the information level.

The boundaries approach stems from the work of Wald [22] who developed the sequential probability ratio test (SPRT), initially for the testing of armaments during World War II. In the SPRT the likelihood ratio for a simple alternative hypothesis relative to the null hypothesis is calculated at each interim analysis. The test continues so long as this likelihood ratio falls within some fixed range. Wald derived stopping limits so as to give a test with specified type I error rate and power under the assumption of continuous monitoring. The SPRT has the important optimality property that among all tests with the same type I error rate and power, the SPRT minimizes the expected sample size when either the null or alternative hypothesis holds. Although the expected sample size is minimized by the SPRT, however, the SPRT has no maximum sample size, so that it cannot be guaranteed that the sample size will be below any fixed value. This feature makes the SPRT unsuitable for many clinical trials.

Following the work of Wald [22], a number of alternative forms for boundaries that maintain the overall type I error rate have been proposed. The choice of the form of boundary in this approach is analogous to the choice of spending function in the approach described above, and, as above, trials may be designed with asymmetric (power requirement I) or symmetric (power requirement II) boundaries. Whitehead [10] describes a wide range of such tests, including approximations to the SPRT that do place a limit on the maximum sample size required. One family of boundary shapes that is particularly common in sequential clinical trials is based around the triangular test. If the efficient score statistic is plotted against the observed Fisher information, this test has straight boundaries that form a triangular-shaped continuation region. An example of a double triangular test is illustrated in the example in Section 6. The triangular test approximately minimizes the maximum expected sample size among all tests with the same error rates. Unlike the SPRT the triangular test has a maximum sample size. It can be shown that for a triangular test there is a high probability of stopping with a sample size below that of the equivalent fixed sample size test, so that on average the sample size will be reduced by the use of this sequential design.

The stopping boundaries obtained using the boundaries approach maintain the overall type I error rate under the assumption of continuous monitoring of the test statistic measuring the treatment difference. In practice, monitoring is necessarily discrete, even if an interim analysis is conducted after observation of every patient. This means that if the critical values from the boundaries approach are used, the type I error rate will be less than the planned level. Whitehead [10] has proposed a correction, known as the *Christmas tree correction*, to modify the continuous boundaries to allow for the discretely monitored sample path. This correction allows interim analyses to be made at any time provided that the timing is not dependent on the observed treatment difference.

### 4.5 Analysis after a Sequential Trial

At the end of a sequential trial a final analysis of the data observed should be conducted. This analysis should provide a $p$ value for testing the null hypothesis that there is no difference between the experimental treatment and the control, and a point estimate and confidence interval for the difference between the treatments,

usually as measured by the primary parameter of treatment difference discussed above.

The fact that a sequential stopping rule has been used means that many of the standard analysis methods that would be employed after a fixed sample sized trial are no longer valid. Facey and Lewis [23] reported in 1998 that a standard analysis is performed inappropriately in many sequential trials. This is hopefully now changing.

Suppose that a sequential trial stopped at some interim analysis with the upper critical value exceeded by the test statistic measuring observed treatment difference, leading to the conclusion that the experimental treatment was superior to the control treatment. The trial has stopped precisely because of the large observed value of the treatment difference. This means that standard unbiased estimates of treatment difference will, on average, overestimate the true value of the treatment difference. In a similar way, the $p$ value from a standard analysis will, on average, be too small, that is, it will tend to overstate the evidence against the null hypothesis. Special methods of analysis are therefore required to allow for the interim analyses that have been conducted in a sequential trial.

The meaning and interpretation of the $p$ values, point estimates, and confidence intervals obtained after a sequential clinical trial are the same as for a fixed sample size trial, but a method must be employed in their calculation that is valid for the sequential stopping rule used. A number of methods of analysis have been proposed. Most are based on an ordering of all possible data sets to reflect which are considered to provide strongest evidence against the null hypothesis being tested. Further details are given by Whitehead [10] and Jennison and Turnbull [11]. The implementation of these methods in commercially available software, as described in more detail in Section 5, enables the easy conduct of a valid analysis following a sequential trial.

### 4.6 Monitoring and Analysis of More Than One Endpoint

In a clinical trial it may be the case that other endpoints in addition to the primary endpoint are important in the clinical assessment of a treatment. If these endpoints are only to be analyzed at the end of the study after complete data on all patients are available, then they are usually termed *secondary endpoints*. No formal monitoring of these is conducted during the trial. If, however, one or more of the endpoints can really be regarded as additional primary endpoints that are important in determining whether a study should stop or continue, then further statistical methodology is required. There are two general approaches to monitoring these *co-primary endpoints* depending on the nature of the endpoints involved.

If several endpoints are measuring a similar aspect of treatment performance, then it may be acceptable to demonstrate efficacy in a collective way across the endpoints. Combining the various endpoints together into a single global measure and then using methods already described in this chapter would then be a suitable approach. As an example, consider the therapeutic area of stroke. There is no single endpoint that is universally accepted. Outcomes of interest include the Barthel index, the modified Rankin score, the Glasgow outcome scale, and the National Institutes of Health (NIH) stroke scale. Investigators do not believe that a positive result in terms of a single one of those outcomes is sufficient. Tilley et al. [24]

describe using a global test statistic in precisely this indication and discuss the advantages and disadvantages of such an approach.

In some indications, with some endpoints, it is not clinically meaningful to combine the endpoints into a single measure. Examples include the need to demonstrate efficacy for two outcomes to gain licensing, such as in Alzheimer's disease where it is generally necessary to consider both mental and physical aspects of a patient's progress. The simultaneous monitoring of efficacy and safety responses would be another example. In these instances, the endpoints should be kept separate and the correlation between them accounted for in the design and analysis of any sequential trial. Due to the complexity of computations, most authors have concentrated on developing *bivariate* methodology, that is, for the case of two co-primary endpoints, see, for example, Jennison and Turnbull [25], Cook and Farewell [26], and Todd [27].

## 5 IMPLEMENTATION OF SEQUENTIAL DESIGNS

As illustrated in Section 4, there are a number of different approaches to the specification of a sequential design and in particular the form of a stopping rule. When considering the implementation of such methodology, the most important issues to focus upon are the reasons why it is desirable to either stop or continue the trial at an interim analysis. Reasons for stopping were outlined above and may include evidence that the experimental treatment is obviously better than the control, evidence that the experimental treatment is already obviously worse, or indication that there is little chance of showing that the experimental treatment is better than the control so that it is considered futile to continue. Reasons for continuing may include belief that a moderate advantage of the experimental treatment is likely and it is desired to estimate this magnitude carefully, or evidence that the event rate is low and more patients are needed to achieve required power. Criteria such as these will first determine the symmetry requirement that is appropriate for the study under consideration, that is, whether an asymmetric (power requirement I) or a symmetric (power requirement II) design should be considered. Once this has been established, attention turns to the specific properties of different tests within a broad category. A choice between the tests is then made based upon consideration of likely sample sizes under various possible treatment effect scenarios. The wide range of stopping rules now available allow sequential designs to be devised for testing *superiority*, *noninferiority*, *equivalence*, and even formal *safety* aspects of clinical trials. As discussed above, some more complex designs even aim to deal with both efficacy *and* safety aspects in a combined stopping rule.

The availability of appropriate designs is just one element of enabling the implementation of sequential methodology. The key requirement for widespread take-up of the techniques is access to software. There are four major commercial software packages currently available. The package PEST [28] is based on the boundaries approach. The package EaSt [29] implements the spending function approach. An addition to the package S-Plus is the S+SeqTrial module [30], which also implements the spending function approach, in this case for a family of designs based on the methodology described by Kittelson and Emerson [31]. The package AddPlan (see www.addplan.com) is based on the adaptive design approach mentioned in Section 7. If a study is to be a comparison of two treatments in respect of a single primary endpoint, with the objective of discovering whether one treatment is superior, non-

inferior, or equivalent to the other, then it will be possible to implement a suitable sequential method using one of the available packages.

When planning to include interim analyses in any clinical trial, the implications of introducing a stopping rule need to be thought through carefully in advance of the study. All parties involved in the production of the protocol should be consulted on the choice of clinically relevant difference, specification of an appropriate power requirement, and the selection of a suitable stopping rule. The operation of any sequential procedure should be clearly described in the statistical section of the trial protocol. Once the trial is underway, it is extremely important that the interim results of an ongoing trial are not circulated widely. Such knowledge may have an undesirable effect on the future progress of the study. Whether a treatment looks good or bad as the trial progresses will obviously affect an investigator's attitude toward the trial. For this reason, it is often the case that a DSMB may be established to consider the progress of a sequential trial as well as assess safety data as discussed in Section 2.

If a DSMB is appointed, one of its first duties should be to review the protocol and to scrutinize any proposed sequential stopping rule prior to the start of the trial. The procedure for undertaking the interim analyses should also be finalized in advance. The DSMB would then review results of the interim analyses as they are reported. It is usual for the board to be supplied with full, unblinded information. Ideally, the only other individual to have knowledge of the treatment comparison would be the statistician who performs the actual analyses of the accumulating data. After each interim examination of the data, the DSMB should issue a short report detailing the outcome of its deliberations. The most common outcome of a meeting is likely to be that the study should continue without modification. However, the DSMB may recommend continuation with some protocol modifications, stopping the study due to safety concerns, or stopping as a result of the formal stopping rule for efficacy having been met. An example of the form of report issued by a DSMB following a meeting is given in Figure 4.

Decision making as part of a sequential trial (whether by a DSMB or another party involved in the trial) is both important and time sensitive. A decision taken to stop a study affects both the current trial and impacts on future trials in the same therapeutic area. However, continuing a trial too long puts participants at unnecessary risk and delays dissemination of important results. The issue applies not only to monitoring efficacy data but also to reacting in a timely manner to safety problems. Wondering whether data are accurate and up-to-date makes the decision process harder. It is therefore necessary to have both timely and accurate data. Unfortunately, a trade-off exists. It takes time to ensure accuracy. One option is to establish a "fast-track" system, processing efficacy data and key safety data separately from other information. Fewer data means that they can be validated more quickly. This is a particularly important issue that requires careful thought and planning.

## 6 EXAMPLE: LITHIUM GAMOLENATE IN PATIENTS WITH ADVANCED PANCREATIC ADENOCARCINOMA

The prognosis for pancreatic cancer patients is poor, with an average survival time of a matter of months from diagnosis. Chemotherapy for pancreatic cancer sufferers

Dear

[redacted]

analysis presented by the independent statistics committee, and then held discussions with representatives of the company.

We noted the incidence of severe side effects but acknowledge that this particular form of cancer is classically associated with thrombotic complications!

We were reassured to hear that centers were now treating patients more expeditiously and with greater familiarity and expertise.

Our decision as to whether to continue the trial was *not* an easy one, but we unanimously agree that the trial should continue under close monitoring and we await the next analysis (70 deaths) with interest.

**Other Comments**

- Would it be possible to look statistically at the first few versus the later patients treated at main centers

[redacted]

***FIGURE 4*** *Example letter sent from the DSMB to the Steering Committee.*

offers only very small survival benefits and is associated with considerable side effects. It was essentially felt that there was no standard treatment available. It has been found that unsaturated fatty acids (lithium gamolenate) have an antitumour effect in experimental studies, and in phase II trials few side effects of this treatment were observed. This prompted the conduct of a randomized dose-finding phase III study [32]. It was required to reach a reliable conclusion concerning the optimum dose when considering survival time from randomization.

Patients with a diagnosis of inoperable pancreatic adenocarcinoma were treated with one of three doses of the active treatment, either oral dose, or low or high intravenous doses. When the objectives of the trial were considered, it was decided that a sequential approach was appropriate. The methodology followed was the boundaries approach, as discussed in Section 4. The comparison employed was

between the high intravenous (IV) dose and the oral dose. The plan was to recruit patients into the study until a sufficiently large difference in the survival rate was seen between these two doses. Analyses involving the low dose IV treatment were considered secondary to this main analysis. The study was designed to have 90% power to detect a difference in median survival of 4 months between the oral dose and the high dose treatments as significant at the 5% level. The reference median survival for oral treatment was taken to be 120 days.

In evaluating the appropriate dose of the treatment, it was desirable to stop the trial as soon as there was sufficient evidence to indicate that either dose was significantly superior to the other. If there was no difference between the doses, then it was also important to distinguish this quickly. In the latter case, further development of oral dose could be justified as this is a less invasive form of the treatment than the intravenous administration. A sequential procedure that satisfies these requirements and has smaller expected sample sizes than the equivalent fixed sample test for any size of treatment difference is the double triangular test [10].

The data concerning survival times following entry into the trial were modeled as survival data, with the difference between the two treatment groups measured by the log hazard ratio. The statistic signifying the difference between the two doses seen so far was taken to be the efficient score for the log hazard ratio. This is the usual log-rank test for survival data, which will be denoted by $Z$. The statistic measuring the amount of information upon which the comparison was based will be denoted by $V$. This is the variance of $Z$ and is approximately one quarter the number of deaths. An independent data and safety monitoring board was established to monitor the progress of the trial at the interim analyses. Figure 5 shows the outcome of five interim analyses. On the diagram the inner dotted boundaries show the Christmas tree correction for discrete looks. These form the stopping boundary, so that the trial should be stopped when one of these values is reached.

*Z*: Efficient score statistic measuring the treatment difference between high and oral doses

*V*: Statistic measuring the information on which the comparison is based

***FIGURE 5*** *Sequential plot for the trial of lithium gamolenate.*

A total of 278 patients were recruited to the trial. Of these 93 patients received oral dose, 90 patients received low dose, and 95 patients received high dose. The log-rank statistic $Z$ crossed the boundary, which indicated that the oral dose was significantly superior to high dose, which was actually contrary to expectations. This occurred at the fourth interim analysis, and recruitment to the trial was stopped at this time. Continuing follow-up of patients already recruited when the trial stopped led to one further *overrunning* analysis, the results of which are also illustrated in Figure 5. A final analysis of the data was conducted using the computer package PEST [28]. The $p$ value obtained was 0.03, a significant result in favor of the oral dose. Median survival after oral treatment was 129 days, while after high dose treatment it was 94 days.

## 7 RESPONSE-DRIVEN AND ADAPTIVE DESIGNS

In the methodology described in detail in Sections 4 and 5 and illustrated by the example, a single decision is made at each interim analysis: whether the trial should be stopped or should continue to the next interim analysis. Much more general sequential methods can be envisaged in which many aspects of a clinical trial design are reconsidered on the basis of the results from the interim analyses. Decisions could be made after each interim analysis regarding, for example, how many patients should be recruited to the next stage of the trial, whether treatment arms should be dropped from a multiarmed clinical trial, which doses should be used for the treatment of the next group of patients in a dose-finding study, or how the treatment allocation ratio might be changed to favor an apparently superior treatment, in addition to the decision of whether or not to stop the trial. Such general methods are often referred to as *response-driven*, *response-adaptive*, or *data-dependent* designs. They are also sometimes called *sequential designs* or *adaptive designs*, although increasingly these terms are reserved for the methods described in Section 4 and methods based on the work of Bauer and Köhne [33], which are described in the next paragraph, respectively.

A statistical approach for clinical trials that compare two treatments that allows more flexibility than the sequential methods described in Section 4 is the *adaptive design* approach [33]. In this approach, a $p$ value is obtained at each interim analysis to test the null hypothesis that there is no difference between the two treatments on the basis of the new data obtained since the previous analysis. The $p$ values from the different interim analyses are then combined by taking their product, and the value of this product is used to decide whether or not to stop the trial and whether the experimental treatment is superior to the control treatment at the end of the trial. Provided the data from the different stages of the trial are independent, any adaptation of the trial can be conducted without increasing the type I error rate. This method thus provides considerable flexibility in terms of design modification while still enabling valid inference to be drawn. It has been shown, however, that if the flexibility is not utilized, there is a slight reduction in power relative to the sequential methods described in Section 4 [34]. Further details of the adaptive design approach are given, together with a review of recent advances, by Posch et al. [35].

Although there has been much interest in the methodology for more general response-driven designs, there has been relative little use of such approaches in

practice. There are two main areas where such designs have been used. The first area is that of small two-arm studies that attempt to modify treatment allocation toward the treatment observed to be more effective. These methods extend the *play-the-winner* designs in which an interim analysis comparing the two treatments is made after observation of each patient, and the next patient is treated with the treatment currently observed to be most effective. A review of statistical methods for the design and analysis of such studies is given by Rosenberger [36].

The second area where response-driven designs have been used is in phase I dose-finding studies. In these studies the aim is to identify a dose that leads to an acceptably low risk of some adverse event in the trial subjects, who may be patients or healthy volunteers. Subjects are often treated in small groups, or *cohorts*, perhaps of three subjects, and the number of subjects to demonstrate the adverse event is recorded. The responses from each cohort are used to decide the dose level or levels to be used for the next cohort. Reviews of methodology for studies of this type are given by Cavalli and Sessa [37] and Whitehead et al. [38].

## 1 INTRODUCTION

Mainly in response to ethical and cost concerns, it has become a common practice that clinical trials, especially phase III studies comparing the efficacy of two or more treatment agents, are monitored using the so-called *group sequential testing procedures*. In a group sequential clinical trial a set of stopping boundaries are usually specified for a test statistic at a few time points, either in terms of real calendar time or statistical information. The stopping boundaries are chosen in a way that the type I error (false-positive) and type II error (false-negative) rates are controlled at the desired levels. In the past several decades, extensive research efforts have been devoted to the determination of these stopping boundaries, resulting in a number

of popular methods such as those developed by Pocock [1], O'Brien and Fleming [2], Lan and DeMets [3], Whitehead and Stratton [4], and Jennison [5], to name a few. Jennison and Turnbull [6] and Proschan, and co-workers [7] provide excellent overview of these group sequential methods.

Statistically speaking, the primary aim of a clinical trial is to test the null hypothesis that there is no significant difference between treatment agents under investigation, while maintaining a satisfactory statistical power if certain treatment difference indeed exists. A sequential clinical trial should be terminated as soon as the monitoring test statistic, derived based on the so-termed *primary endpoint*, reaches a stopping boundary, although the Data Safety and Monitoring Board (DSMB) may recommend the trial be terminated earlier before reaching a boundary or be continued after reaching a stoping boundary, based on various reasons, such as safety concerns. Once a boundary is reached and the trial stops, a decision can then be made on whether the null hypothesis should be rejected and one treatment agent is better than the other.

When reporting clinical trial findings, it is not sufficient to simply state *rejection* or *no rejection* of the null hypothesis. Point estimates and confidence intervals, which measure the magnitude of the treatment difference, and $P$ values, which give the strength of the trial against the null hypothesis, should also be provided as an integrated part of the trial findings. However, from a frequentist's point of view, the usual maximum-likelihood approach, which provides (asymptotically) most efficient fixed sample-size inference, yields biased estimation due to the randomness of the observed sample size and its dependence with the test statistic and is thus no longer appropriate. In fact such randomness and dependence have been long well recognized as the cause of the type I error inflation when the usual fixed-size critical values are used repeatedly at each interim analysis. Unfortunately, when it comes to inferential analysis following a sequential trial, randomness and dependence are often ignored and the usual maximum-likelihood inference is conducted.

In what follows, we summarize several popular approaches developed in the literature to construct point and interval estimation and $P$ values with respect to the primary endpoint following the termination of a sequential phase III trial. A brief overview will also be given to methods for inference concerning a secondary endpoint. Sequential phase II clinical trials in which interim monitoring is based on a Bernoulli variable (binary outcome) will not be discussed. However, most concepts and principles described here apply analogously to analysis following a sequential phase II trial.

## 2 BROWNIAN MOTION PARADIGM IN SEQUENTIAL TRIALS

A phase III clinical trial is usually monitored based on a Brownian motion $X(t)$ with drift $\delta$, provided that the sample size is large enough so that the test statistics can be well approximated by a Brownian motion. A Brownian motion $X(t)$ with drift $\delta$ satisfies several nice properties: $X(0) = 0$, and $X(t) \sim N(\delta t, t)$ for $t > 0$. Furthermore, for any $0 < t_1 < t_2 < \cdots < t_k < \infty$, $X(t_1)$, $X(t_2) - X(t_1)$, $\ldots$ , $X(t_k) - X(t_{k-1})$ are mutually independent, a proposition so well termed as *independent increments*, each normally distributed as $X(t_j) - X(t_i) \sim N(\delta(t_j - t_i), t_j - t_i)$ and $\mathrm{cov}(X(t_j), X(t_i)) = t_i$, for $i < j$. In practice, $t$ is usually the Fisher information and $X(t)$ is usually a test statistic, and

the drift parameter $\delta$ is a measure of treatment difference with $\delta = 0$ if there is no treatment difference.

To give the readers a flavor of how such Brownian motion may be constructed, let us consider the case of comparing, with equal allocation, two normal means with known common variance. Let $X_{1A}, \ldots, X_{nA}$ be the outcomes from $n$ subjects allocated to treatment $A$, and $X_{1B}, \ldots, X_{nB}$ be that to treatment $B$. Assume that $X_{iA} \sim N(\mu_A, \sigma^2)$ and $X_{iB} \sim N(\mu_B, \sigma^2)$. The null hypothesis is $H_0$: $\mu_A - \mu_B = 0$. The standardized test statistic is $Z_n = \sum_{i=1}^{n}(X_{iA} - X_{iB})/\sqrt{2n\sigma^2}$, which follows standard normal $N(0, 1)$, and a two-sided test with level of significance $\alpha$ rejects the null hypothesis if $|Z_n| > \Phi^{-1}(1 - \alpha/2)$, where $\Phi$ is the standard normal distribution. To put this into a Brownian motion framework, we redefine (after a little bit pleasant algebraic manipulation) the test statistic as

$$X = \sqrt{\frac{n}{2\sigma^2}} Z_n$$

then $X$ resembles a Brownian motion $X(t)$ with drift $\delta = \mu_A - \mu_B$ and in this example the (discrete) time $t = n/(2\sigma^2)$.

This Brownian motion paradigm applies to the two-arm comparison of many clinical endpoints such as proportions, ordinal data, and survival rates. Whitehead [8] presented a nice review of this structure and named it *a unified theory*. See also Lan and Zucker [9] and Proschan and co-workers [7].

With this framework, a group-sequential clinical trial can be formulated as interim monitoring of a Brownian motion $X(t)$ with drift $\delta$ at several discrete time points $t_1, \ldots, t_K$, where $K$ is the prespecified number of interim and looks to be carried out during the whole course of the trial. For each look $k$, let $C_k = (a_k, b_k)$ be the continuation region and $S_k = (-\infty, a_k] \cup [b_k, \infty)$ be the stopping region, where $a_k < 0 < b_k$ define the lower and upper boundary of the sequential test. Then the trial stops at the $k$th look if the $k$th boundary is reached first, that is, if

$$X(t_i) \in C_i, i \le k-1 \qquad X(t_k) \in S_k$$

Upon stopping at the $k$th interim look, we observe two statistics, the stopping time $T = t_k$ and the position of the Brownian motion $X(T) = X(t_k)$. These two statistics together are sufficient for the drift parameter $\delta$ and hence inference on $\delta$ can be based solely on $(T, X(T))$. The joint distribution $f_\delta(k, x)$ of $(T, X(T))$ at $(T, X(T)) = (t_k, x)$ is $f_\delta(k, x) = f_0(k, x)\exp\{x\delta - \frac{1}{2}t_k\delta^2\}$, where the baseline functions $f_0(k, x)$ can be computed numerically using the following recursive formulas:

$$f_0(1, x) = \frac{1}{\sqrt{t_1}}\phi\left(\frac{x}{\sqrt{t_1}}\right)$$

and

$$f_0(k, x) = \frac{1}{\sqrt{t_k - t_{k-1}}}\int_{C_{k-1}} \phi\left(\frac{x-s}{\sqrt{t_k - t_{k-1}}}\right) f_0(k-1, s)\,ds \qquad k = 2, \ldots, K$$

where $\phi$ is the standard normal density function. Thus, for a statistic $h(T, X(T))$, its expectation is given by

$$E(h(T, X(T))) = \sum_{k=1}^{K} \exp\left\{-\frac{1}{2} t_k \delta^2\right\} \int_{S_k} h(k, x) f_0(k, x) \exp\{x\delta\} dx \tag{1}$$

## 3 ESTIMATING MAGNITUDE OF TREATMENT DIFFERENCE

The maximum-likelihood estimate of $\delta$ is $\hat{\delta}_{\mathrm{ML}}(T, X(T)) = X(T)/T$, the same form as that following a fixed-size test ($K = 1$). However, its statistical properties change substantially due to the randomness of $T$ and further complication of the dependence between $T$ and $X(T)$. As a consequence, many optimal properties that the estimate enjoys under fixed-size sampling vanish under sequential sampling. For instance, the maximum-likelihood estimate is no longer unbiased. When $K = 2$, the bias function $b(\delta)$ can be expressed in a closed form as

$$b(\delta) = \sqrt{t_1}\left(\frac{1}{t_1} - \frac{1}{t_2}\right)\left\{\phi\left(\frac{b_1 - \delta t_1}{\sqrt{t_1}}\right) - \phi\left(\frac{a_1 - \delta t_1}{\sqrt{t_1}}\right)\right\}$$

See Emerson [10].

A naive approach to reduce the bias is to subtract from $\hat{\delta}_{\mathrm{ML}}$ the maximum-likelihood estimate of the bias $b(\delta)$, yielding an estimate as $\hat{\delta} = \hat{\delta}_{\mathrm{ML}} - b\left(\hat{\delta}_{\mathrm{ML}}\right)$. Since $\hat{\delta}_{\mathrm{ML}}$ is biased for $\delta$, $b\left(\hat{\delta}_{\mathrm{ML}}\right)$ may not be a good estimate for $b(\delta)$. Therefore, the resulting estimate $\hat{\delta}$ may not be a good estimate for $\delta$. Whitehead [11] instead suggested replacing $\delta$ in the bias function by the so-called *bias-adjusted estimate*, $\hat{\delta}_{\mathrm{W}}$, to be solved from the equation

$$\hat{\delta}_{\mathrm{W}} + b\left(\hat{\delta}_{\mathrm{W}}\right) = \hat{\delta}_{\mathrm{ML}}$$

Whitehead [11] initially proposed his bias-adjusted estimate in the context of *fully sequential tests* with parallel or triangular stopping boundaries. He presented substantial numerical evidence for both boundaries that the bias-adjusted estimate indeed has smaller bias (and mean-squared error as well!) than the maximum-likelihood estimate.

However, the idea is quite general and applicable in reducing the bias of an estimate, so long as the bias function of the estimate can be worked out. The performance of such estimate depends on the shape of the bias functions. If the bias function of the estimate is nondecreasing and can be differentiated at least twice, then the bias-adjusted estimate has uniformly smaller mean-squared error than the initial estimate; see Whitehead [11] and Liu [12].

Emerson and Fleming [13] investigated Whitehead's bias-adjusted estimate in the context of group-sequential tests and compared with an unbiased estimate constructed in their study using conditioning argument:

$$\hat{\delta}_{\mathrm{EF}} = E\left\{\frac{X(t_1)}{t_1}\middle| (T, X(T))\right\}$$

This is indeed an unbiased estimate since the expectation of $X(t_1)/t_1$ is always $\delta$, regardless at which stage the test stops. Although $\hat{\delta}_{EF}$ nullifies the bias, numerical results from Emerson and Fleming [13] showed that in general it has a larger mean-squared error than Whitehead's bias-adjusted estimate, a sacrifice to be made for enforcing unbiasedness. As expected, the two estimates both have smaller bias and mean-squared error than the maximum-likelihood estimate, as considerable numerical results have shown. However, analytic results are limited, perhaps due to the complicated forms of the density functions, on the statistical properties and comparison of the two estimates.

More can be said about how the sequential sampling [resulting in the randomness of $T$ and dependence between $T$ and $X(T)$] changes the statistical property of a parameter estimate. Under fixed-size sampling, the maximum-likelihood estimate $\hat{\delta}_{ML}$ is the unique unbiased estimate based on the sufficient statistic $X(T)$ ($T$ is a constant now) and has uniformly minimum variance among the unbiased estimates, a fact attributed to the well-known Rao–Blackwell theorem. Under group-sequential sampling, however, as shown in Liu and Hall [14], there are infinitely many sufficient-statistic-based unbiased estimates and none, $\hat{\delta}_{EF}$ particularly included, has uniformly minimum variance. Only when restricted to unbiased estimates that are independent of future stopping rules does $\hat{\delta}_{EF}$ have uniformly minimum variance.

## 4 CALCULATION OF *P* VALUES AS EVIDENCE AGAINST NULL HYPOTHESIS

The $P$ values in a clinical trial measure the statistical strength (evidence) against the null hypothesis that there is no difference between treatment agents. It is defined as the probability, computed under the null hypothesis, of obtaining data that yields a statistic of interest being at least as extreme as the observed value of the statistic. Thus, smaller $P$ values correspond to more extreme data from which the statistic is computed and reflect stronger evidence against the null hypothesis.

In a fixed-size clinical trial ($K = 1$ and $t_1$ is a constant), the calculation and interpretation of the $P$ values is more straightforward and much less problematic. So long as the statistic of interest is a monotone function of $X(t_1)$, as is true for most cases, the upper- and lower-tail $P$ values are given by, respectively,

$$P_{\delta=0}(X(t_1) > \tilde{x}) = 1 - \Phi\left(\frac{\tilde{x}}{\sqrt{t_1}}\right) \qquad P_{\delta=0}(X(t_1) < \tilde{x}) = \Phi\left(\frac{\tilde{x}}{\sqrt{t_1}}\right)$$

where $\tilde{x}$ is the realization (observed value) of $X(t_1)$. Doubling the smaller of the upper- and lower-tail $P$ values yields the two-sided $P$ value, which, because of symmetry, is given by

$$P \text{ value} = P_{\delta=0}(|X(t_1)| > |\tilde{x}|) = 2\left\{1 - \Phi\left(\frac{\tilde{x}}{\sqrt{t_1}}\right)\right\}$$

Unfortunately, the definition of a $P$ value in a group-sequential trial is not as clear as it would be in a fixed-size trial and sometime brings considerable ambiguity and confusion to many practitioners. What does it mean by data being *extreme*? What statistic should be used in defining *extreme*? The problem comes from the fact that, instead of summarizing the data by a one-dimensional sufficient statistic $X(t_1)$ in a fixed-size trial, we now have to summarize the data by two dependent statistics, $T$ and $X(T)$, both of which contain information on the treatment difference $\delta$. A sample path (or data) with smaller $T$ (earlier stopping) and larger $X(T)$ is without doubt more extreme than a path with larger $T$ and smaller $X(T)$. But what about a path with $T$ and $X(T)$ both smaller and a path with $T$ and $X(T)$ both larger? In a word, how should the points $(T, X(T))$ in the sample space in a group-sequential trial,

$$\Omega = \{X(t_1) \in S_1\} \cup \left[\cup_{k=2}^{K} \{X_{t_i} \in C_i, i < k, X_{t_k} \in S_k\}\right]$$

be ordered so that *being extreme* is well defined? Is there an ordering that is better than the others, statistically and/or practically?

A number of popular orderings have been proposed in the literature, most based on a one-dimensional statistic $s(T, X(T))$ defined on the sample space $\Omega$. A point $(t_i, X(t_i))$ is more extreme than another point $(t_j, X(t_j))$ if $s(t_i, X(t_i)) > s(t_j, X(t_j))$. With this ordering, suppose the trial stops at stage $k$ with $X(t_k) = \tilde{x}$, then the upper-tail $P$ value is given by

$$P_{\delta=0}\{s(T, X(T)) > s(t_k, \tilde{x})\}$$

which can be computed numerically using the recurse density functions. The lower-tail $P$ value is given accordingly, and the two-sided $P$ value is twice the smaller of the two $P$ values.

Roser and Tsiatis [15] defined $s(T, X(T))$ to be the score statistic (the position of the Brownian motion) $X(T)$, while Chang [16] suggested using the standardized test statistic $X(T)/\sqrt{T}$, and Emerson and Fleming [13] investigated ordering based on the maximum-likelihood estimate $X(T)/T$.

The so-called *stagewise ordering* (e.g., Siegmund [17], Fairbanks and Madsen [18], and Tsiatis and co-workers [19] is somewhat different from the above three orderings and is not based on a one-dimensional statistic. A data point $(t_i, X(t_i))$ is more extreme than the other $(t_j, X(t_j))$ if it reaches the upper or lower boundary earlier $[i < j$ and $X(t_i) > b_i$ or $< a_i]$. For data points with the same information time, the one with larger value of $X(t)$ is more extreme.

All four orderings reduce to the same one in the fixed-size setting. However, there are no deterministic results on which ordering is better than the others. Some argue that the stagewise ordering is more preferable since it yields $P$ values in agreement with the decision from the hypothesis testing; it is less than the significance level $\alpha$ if and only if the null hypothesis is rejected. Moreover, the stagewise ordering does not depend on the stages beyond the stopping one, making it applicable in some more flexible designs in which the information time points at which interim analysis is conducted are not specified in advance. See Jennison and Turnbull [6].

## 5 CONSTRUCTION OF CONFIDENCE INTERVALS

A confidence interval of $\delta$ with level $(1-\alpha)$ is an interval with lower bound $\delta_L^* = \delta_L^*(T, X(T))$ and upper bound $\delta_U^* = \delta_U^*(T, X(T))$ such that for any $\delta$

$$P_\delta\{\delta_L^* < \delta < \delta_U^*\} \geq 1-\alpha$$

One approach to construct such an interval is to use an ordering of the sample space described previously for calculating $P$ values. Let the terminal data be $(t_k, \tilde{x})$. Then $\delta_L^*$ is the drift value at which the probability is half $\alpha$ of observing data being at least as extreme as $(t_k, \tilde{x})$, and $\delta_U^*$ is the drift value at which the probability is $1-\alpha/2$ of observing data being at least as extreme as $(t_k, \tilde{x})$. That is, $\lambda(\delta_L^*; t_k, \tilde{x}) = \alpha/2$ and $\lambda(\delta_U^*; t_k, \tilde{x}) = 1-\alpha/2$, where

$$\lambda(\delta; t_k, \tilde{x}) = P_\delta\{(T, X(T)) \text{ is at least as extreme as } (t_k, \tilde{x})\}$$

In order for the two equations to yield an interval, the function $\lambda(\delta; t_k, \tilde{x})$ needs to be increasing in $\delta$ for any given data point $(t_k, \tilde{x})$. With such monotonicity each equation has a unique solution and $\delta_L^* < \delta_U^*$ holds. If the $\lambda$ function is nondecreasing, then $\delta_L^*$ can be set to be $\{\delta: \lambda(\delta; t_k, \tilde{x}) = \alpha/2\}$ and $\delta_U^*$ to be $\{\delta: \lambda(\delta; t_k, \tilde{x}) = 1-\alpha/2\}$. It can be shown analytically that Emerson and Fleming's [13] ordering and the stagewise ordering both yield increasing $\lambda$ functions; see Emerson [10] or Hall and Liu [20] for the former and Jennison and Turnbull [6, Chapter 8] for the latter. There is no analytic results on this matter for the other two orderings though limited numerical results do not seem to support the monotonicity property.

Jennison and Turnbull [6, Chapter 8] discussed several criteria for defining a good confidence interval such as agreement with the hypothesis testing results and inclusion of the maximum-likelihood estimate. They come to a conclusion that the stagewise ordering gives a more preferable confidence interval, which, in addition, is the only feasible method to use when future information time for interim analysis is not specified.

Woodroof [21] proposed a different approach to construct a confidence interval by modifying the fixed-size procedure to take the bias into consideration. Write $Z(\delta) = (X(T) - T\delta)/\sqrt{T}$. In fixed-size sampling, $Z$ is normally distributed with zero mean and unit variance and serves as a pivot to construct the usual $(1-\alpha)$-level confidence interval with limits $X(T)/T \mp \Phi^{-1}(1-\alpha/2)/\sqrt{T}$. In a group-sequential sampling, this pivot no longer has a standard normal distribution, so a certain adjustment is needed. A new pivot is defined as $Z(\delta) = (Z(\delta) - \mu(\delta))/s(\delta)$ where $\mu(\delta)$ and $s(\delta)$ are the mean and standard deviation function of $Z(\delta)$, respectively. If we assume that this new pivot approximately follows a standard normal distribution, then an approximate $(1-\alpha)$-level confidence interval for $\delta$ has confidence limits being

$$\left\{\frac{X(T)}{T} - \frac{\hat{\mu}}{\sqrt{T}} \mp \frac{\hat{s}}{\sqrt{T}}\Phi^{-1}\left(1-\frac{\alpha}{2}\right)\right\}$$

where $\hat{\mu}$ and $\hat{s}$ are proper estimates of $\mu(\delta)$ and $s(\delta)$, respectively, which are often obtained with $\delta$ replaced by its maximum-likelihood estimate.

Unlike the confidence intervals based on a sample space ordering, the above pivotal method does not always guarantee the exact coverage probability of $1 - \alpha$. However, it works pretty well in most cases, and the coverage probability of the resulting confidence intervals are quite close to the nominal level of $1 - \alpha$.

We have seen applications of the orderings of the sample space to constructing confidence intervals and calculating $P$ values. Another usage of a proper ordering of the sample space is to compute a *median-unbiased* estimate $\hat{\delta}_M = \hat{\delta}_M(T, X(T))$ of $\delta$ such that

$$P_\delta\left\{\hat{\delta}_M(T, X(T)) < \delta\right\} = P_\delta\left\{\hat{\delta}_M(T, X(T)) > \delta\right\} = \frac{1}{2}$$

That is, a median-unbiased estimate has equal chances to over- or underestimate the parameter. (In contrast, the usual unbiased estimates such as $\hat{\delta}_{EF}$ are referred to as *mean-unbiased* estimates, if such distinction needs to be made.) For an ordering of sample space with monotonicity property, the corresponding median-unbiased estimate at $(t_k, \tilde{x})$ can be found by solving for $\delta$ the equation:

$$\frac{1}{2} = \lambda(\delta; t_k, \tilde{x}) = P_\delta\{(T, X(T)) \text{ is at least as extreme as } (t_k, \tilde{x})\}$$

Emerson and Fleming [13] investigated the bias and mean-squared error of the median-unbiased estimates based on certain orderings. Compared with the bias-adjusted estimate $\hat{\delta}_W$ and the unbiased estimate $\hat{\delta}_{EF}$, the median-unbiased estimates in general tend to have larger bias, often coupled with larger mean-squared error as well.

## 6 INFERENCE CONCERNING SECONDARY ENDPOINT

Termination of a sequential clinical trial is based on the *primary endpoint*, such as patients' survival in a cancer trial. In contrast, a *secondary endpoint*, such as patients' disease-free survival or treatment × strata interaction, refers to an endpoint whose values are also observed from each patient along with the primary endpoint but do not contribute in any way to the termination of the trial. The secondary endpoints are usually analyzed only after the trial stops, though they may be evaluated at certain interim analysis, and such evaluation plays no role in sequential monitoring of the trial.

A secondary endpoint is usually correlated with the primary endpoint since they both are observed from the same patients. Due to the correlation, the usual likelihood analysis should also be adjusted for the random stopping of the trial so that a valid inference on secondary endpoints can be made. For most trials the primary and a secondary endpoint can be put into a random-sampling framework and be (asymptotically) modeled as two correlated Brownian motions with constant (often assumed to be known) correlation and proportional information time. The first Brownian motion, as given in the previous sections, governs the stopping of the trial, and the second one summarizes the observations of the secondary endpoint with

its drift parameter usually measuring the difference in the endpoint between treatment arms. For this drift parameter, Whitehead [22] constructed a bias-adjusted estimate to reduce the bias of the maximum-likelihood estimate, and Liu and Hall [23] investigated its unbiased estimates. Certain confidence intervals are developed by Whithead and co-workers [24] using Woodroofe's pivotal method; these confidence intervals can also be used for testing hypotheses concerning the secondary endpoints.

Not all secondary endpoints can be modeled (asymptotically) with the primary endpoint as two Brownian motion with constant correlation coefficients. Yakir and Hall [25] and Hall and Yakir [26] gave examples that do not satisfy this model. One example is that a sequential trial with staggered entry is carried out to compare the survival rate of two treatment arms based on the log-rank statistic. Upon termination of the trial, one wants to know whether treatment × gender interaction exists. In these examples, the primary and secondary endpoints are modeled as two Gaussian processes with correlation being a function of the information time. Hall and Yakir [26] derived distributional theory and certain optimal properties to construct point estimates and confidence intervals of the parameters associated with the secondary endpoint.

The inference procedures discussed so far are parametric in nature. Chuang and Lai [27, 28] developed nonparametric methods based on a resampling technique for confidence intervals concerning both the primary and secondary endpoints.

## 1 INTRODUCTION

Evidence-based medicine is a cornerstone of current medical practice. Randomized controlled trials are regarded as the most robust form of evidence-based medicine. An appreciation of statistical methods is fundamental to understanding randomized trial methods and results.

A randomized controlled trial aims to provide unbiased treatment effect regarding the efficacy and safety of a medicinal product or a therapeutic procedure. The observed treatment effect, however, may represent the "true" difference between the new drug and the comparative treatment or it may not. Therefore, if the trial were repeated with all the available patients in the world, then the outcome would either be the same as the trial (a true result) or different (making the trial result a chance event, or an erroneous false result). Understanding the possible sources of erroneous results is critical in the appreciation of clinical trials. The reasons for erroneous results fall into three main categories.

- First, the trial may have been biased in some predictable fashion.
- Second, it could have been contaminated (confounded) by an unpredictable factor.
- Third, the result may simply have occurred by chance.

### 1.1 Bias and Systematic Errors

Bias can influence a trial by the occurrence of systematic errors that are associated with the design, conduct, analysis, and reporting of the results of a clinical trial. Bias can also make the trial-derived estimate of a treatment effect deviate from its true value [1, 2]. The most common types of bias in clinical trials are those related to subject selection and outcome measurement. For example, if the investigators are aware of which treatment a patient is receiving, it could affect the way they collect information on the outcome during the trial, or they might recruit patients in a way that could favor the new treatment, resulting in a selection bias.

In addition, exclusion of subjects from statistical analysis because of noncompliance or missing data could bias an estimate of the true benefit of a treatment, particularly if more patients were removed from analysis in one group than the other [3, 4]. Much of the advanced design strategies seek to reduce these systematic errors.

### 1.2 Confounding

Confounding represents the distortion of the true relationship between treatment and outcome by another factor, for example, the severity of disease [5]. Confounding occurs when an extra factor is associated with both the outcome of interest and treatment group assignment. Confounding can both obscure an existing treatment difference and create an apparent difference that does not exist.

If we divided patients into treatment groups based on inherent differences (such as mean age) at the start of a trial, then we would be very likely to find the benefit of the new treatment to be influenced by those preexisting differences. For example, if we assign only smokers to get treatment A, only nonsmokers to get treatment B, and then assess which treatment protects better against cardiovascular disease, we might find that the benefit seen with treatment B is due to the lack of smoking in this group. The effect of treatment B on cardiovascular disease development would therefore be confounded by smoking.

Randomization in conjunction with a large sample size is the most effective way to restrict such confounding, by evenly distributing both known and unknown confounding factors between treatment groups. If, before the study begins, we know which factors may confound the trial, then we can use randomization techniques that force a balance of these factors (stratified randomization). In the analysis stage of a trial, we might be able to restrict confounding using appropriate statistical techniques such as stratified analysis and regression analysis [6].

### 1.3 Random Error

Even if a trial has an ideal design and is conducted to minimize bias and confounding, the observed treatment effect could still be due to random error or chance [1, 2, 7]. The random error can result from sampling, biologic, or measurement variation in outcome variables. Since (given specific selection criteria) the patients in a clinical trial are only a sample of all possible available patients, the sample might yet show a chance false result compared to the overall population. This is known as a sampling error. Sampling errors can be reduced by choosing a very large group of patients. Other causes of random error are described elsewhere [2].

Statistical analyses deal with random error by providing an estimate of how likely the measured treatment effect reflects the true effect [7–9]. Statistical testing or inference involves an assessment of the probability of obtaining an observed treatment difference or more extreme difference for an outcome, assuming that there is no difference between treatments. This probability is often called the $P$ value or false-positive rate. If the $P$ value is less than a specified critical value (e.g., 5%), the observed difference is considered to be statistically significant. The smaller the $P$ value, the stronger the evidence is for a true difference between treatments. On the other hand, if the $P$ value is greater than the specified critical value, then the observed difference is regarded as not statistically significant and is considered to be potentially due to random error or chance. The traditional statistical threshold is a $P$ value of 0.05 (or 5%), which means that we only accept a result when the likelihood of the conclusion being wrong is less than 1 in 20. In other words we conclude that only 1 out of a hypothetical 20 trials will show a treatment difference when in truth there is none.

Statistical estimates summarize the treatment differences for an outcome in the forms of point estimates (e.g., means or proportions) and measures of precision [e.g., confidence intervals (CIs)] [7]. A 95% CI for a treatment difference means that the range presented for the treatment effect contains (when calculated in 95 out of 100 hypothetical trials assessing the same treatment effect) the true value of treatment difference, that is, the value we would obtain if we were to use the entire available patient population is 95% likely to be contained in the 95% CI.

Finally, testing several different hypotheses with the same trial (e.g., comparing treatments with respect to different outcomes or for several smaller subpopulations within the trial population) will increase the chance of observing a statistically significant difference purely due to chance [10]. Even examining the difference between treatments at many time points (interim analyses) throughout the length of the trial could lead to a spurious result due to multiple testing [10, 11]. Therefore, the aim should be to plan a trial in such a way that the occurrence of any such errors is minimal.

## 2 TYPES OF DATA, SUMMARY, AND DATA PRESENTATION

### 2.1 Types of Data

Clinical studies compare effects of medical treatment or interventions on two or more groups of subjects. Data are collected, however, at the individual subject or patient level. Data are composed of baseline characteristics such as age, gender, height, weight, and so forth, or of disease factors such as presence of arthritis, coronary disease, or severity of a fracture, or of treatment response variables such as reduction in pain, improvement of disease, or prolongation of life. These data come from variables of different types—either continuous (or quantitative), such as age or hemoglobin levels, or they may be categorical (or qualitative), such as race or gender.

Data can be classified further into four main groups:

- Binary (categorical): for example, sex (male and female)
- Unordered (categorical): for example, race (white, black, other)
- Ordered (categorical): for example, severity (mild, moderate, severe)
- Numerical (continuous): for example, age (in years)

### 2.2 Data Description and Presentation

In clinical studies, data are summarized for presentation by treatment groups using frequency distributions. These present the distribution of both qualitative and quantitative data, summarizing how often each value of a data point is repeated. With quantitative data, we mostly present a grouped frequency distribution. From a frequency table we can appreciate:

- The frequency (number of cases) occurring for each category or interval—for example, number of 70-year-old patients

- The relative frequency (percentage) of the total sample in each category or interval—for example, 70-year-old patients were 10% of the overall sample
- The highest and lowest or the range of possible values from our patient groups—for example, in that group the oldest patient was 96 and the youngest patient was 25

Although a frequency table provides a detailed summary of the distribution of the data, presentation of the distribution in a graph/chart makes the message from the data more informative. The type of graph depends on the type of data. Generally, if the data are categorical, we use a bar graph or a pie chart. If the data are continuous, a histogram or frequency polygon is more appropriate. As well as for the entire study population, the frequency distributions can then be presented for each treatment group. This is a fast way of ascertaining whether there are broad similarities or differences between treatment groups. Later we can use statistical tests to ascertain whether any differences between the groups are significant.

### 2.3 Summarizing Quantitative Variables

Categorical variables may be expressed as percentages and compared between different groups. There is little more that can be done to describe such variables. However, for a quantitative variable we can do more than this. We have other measures with which to summarize the data (summary measures). From the frequency distribution we can calculate the location (or central tendency) that summarizes where the center of the distribution lies and we can also summarize the spread/range (or variation) of the distribution, which describes how widely the values are spread above and below the central value.

There are two measures commonly used to describe the location for the central tendency, depending on whether the distribution is even (such as age) or more biased in one direction (such as physical fitness—many more people are unfit than are Olympic athletes).

- *Mean:* The mean can be calculated by summing all the quantitative observations and divided the sum by the number of observations.
- *Median:* The median is the value that divides the distribution equally. The median is more appropriate for distributions that are skewed, such as physical fitness. When the distribution is symmetrical, the median equals the mean.

There are three measures commonly used to summarize the spread of a variable:

- *Standard deviation:* This gives the average distance of all observations from the mean. The standard deviation has an important role in statistical analysis.
- *Range:* Any data between the lowest and highest values is known as the full range of values.
- *Percentile:* This is the value below which a given percentage of the data observations occur. The most commonly used percentiles are 5 and 95%. Using these overcomes the problem of extreme data values away from the mean or median.

## 3 NORMAL DISTRIBUTION: SYMMETRIC FREQUENCY DISTRIBUTION

### 3.1 What Is a Normal Distribution?

Quantitative variables can range from very small to very large values, and, in some situations, from negative to positive values. Consider the systolic blood pressure (BP) measurements of 1000 subjects participating in a lifestyle survey. The frequency distribution of these systolic BPs is shown in Figure 1. The height of each vertical bar in this graph shows the proportion (or probability) of subjects whose systolic blood level was between the values at the base of the bar. So, if we summed the heights of all the bars in the histogram, we should find that the total of all the proportions is 1. Proportion is the same as the percentage expressed as a fraction over 100%.

The distribution of these blood pressures conforms approximately to a bell-shaped curve or normal distribution typical for common continuous biological measurements. The curve has particular mathematical properties expressed by the

Normal distribution function:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[\frac{-(x-\mu)^2}{2\sigma^2}\right] \qquad \sigma > 0, -\infty < \mu < \infty, -\infty < x < \infty$$

Properties of normal distribution (curve):

The curve has a single peak at the center; this peak occurs at the mean ($\mu$).
The curve is symmetrical about the mean.
The curve never touches the horizontal axis.
The total area under the curve is equal to 1.
The width or shape of the curve is described by the variance ($\sigma^2$), the squared root of which is the standard deviation ($\sigma$).

***FIGURE 1*** *Histogram and fitted normal distribution curve for systolic blood pressures from 1000 subjects.*

equation shown with the curve. This distribution is one of the most important distributions in statistics and is known as the Gaussian distribution [12].

If we have enough values with smaller bars, the heights of these bars would form the bell-shaped curve shown superimposed on the chart. This curve is defined by the mean, or central value ($\mu$), of 149.044 mmHg, and by its spread, or standard deviation ($\sigma$), of 37.317 mmHg.

### 3.2 Properties of Normal Distribution

The properties of a normal distribution are illustrated in the legend of Figure 1. The standard deviation helps to describe the spread of the observations, with about 68% of all observations being captured within one standard deviation at either side of the mean and about 95% of all observations captured within two standard deviations at either side of the mean.

## 4 PRINCIPLES OF STATISTICAL INFERENCE

Let us suppose that it is necessary to measure the average systolic blood pressure (SBP) level of all males aged ≥16 years in the United Kingdom in 2005. For practical and financial reasons, it is not possible to directly measure the SBP of every adult male in the United Kingdom. Instead, we can conduct a survey among a subset (or "sample") of 500 males within this population. Through statistical inference, we can measure the properties of the sample (such as the mean and standard deviation) and use these values to infer the properties of the entire UK adult male population [11–13].

Population properties are usually determined by population parameters (numerical characteristics of a population) that are fixed and usually unknown quantities, such as the mean ($\mu$) and standard deviation ($\sigma$) in a normal distribution $N(\mu,\sigma^2)$ [14, 15]. The statistical properties of the sample, such as the mean ($\bar{X}$) and standard deviation ($S$), can be used to provide estimates of the corresponding population parameters. Conventionally, Greek letters are used to refer to population parameters, while the Roman alphabet is used to refer to sample estimates.

Two strategies that are often used to make statistical inference are [7, 13, 14]:

1. Hypothesis testing
2. Confidence intervals (CIs)

### 4.1 Hypothesis Testing

Statistical inference can be made by performing a hypothesis (or significance) test, which involves a series of statistical calculations [7, 12–14]. In the sample of 500 adult males, the mean SBP ($\bar{X}$) was 130 mmHg, with a standard deviation ($S$) of 10 mmHg. The empirical estimate for the mean SBP of this population from previous medical literature is reported as 129 mmHg (denoted by $\mu_0$). So, we want to know whether there is any evidence that the mean SBP value for all adult males in the United Kingdom in 2005 ($\mu$) is different from 129 mmHg ($\mu_0$).

We start by stating a hypothesis that the population mean SBP for all adult men in 2005 is 129 mmHg, or $\mu = \mu_0$ (i.e., no different to that reported in the medical literature). This is referred to as the null hypothesis and is usually written as $H_0$, representing a theory that has been put forward as a basis for argument [7, 12–14]. The hypothesis test is a means to assess the strength of evidence against this null hypothesis of no difference.

The alternative hypothesis, usually written as $H_a$, is that the mean SBP for the study population is not equal to the specified value, that is, $\mu \neq \mu_0$. Note that under the alternative hypothesis, the 2005 population mean could be higher or lower than the reference mean. The statistical test for the above hypotheses is usually referred to as a two-sided test.

Once the null hypothesis has been chosen, we need to calculate the probability that, if the null hypothesis is true, the observed data (or data that were more extreme) could have been obtained [7, 12–14]. To reach this probability, we need to calculate a test statistic from the sample data (e.g., $\bar{X}$, $S$, and $n$ for quantitative outcomes) using an appropriate statistical method. This test statistic is then compared to the distribution (e.g., the normal distribution) implied by the null hypothesis to obtain the probability of observing our data or more extreme data.

For the SBP data, given the relatively large sample size, we can use the $Z$ test to calculate the value of the test statistic $Z$. The $Z$ test is expressed by the following formula [7, 12–14]:

$$Z = \frac{\bar{X} - \mu_0}{S/\sqrt{n}}$$

This statistic follows a normal standard distribution under the null hypothesis [7, 12–14]. For the SBP data:

- $\bar{X} = 130$ mmHg
- $S = 10$ mmHg
- $n = 500$
- $\mu_0 = 129$ mmHg

Replacing the values in the formula generates $Z = 2.24$. A variety of statistical methods can be used to address different study questions (e.g., comparing treatment difference in means and proportions). The choice of statistical test will depend on the types of data and hypotheses under question [7, 12–14].

Having obtained the appropriate test statistic (in our example, the $Z$ value), the next step is to specify a significance level. This is a fixed probability of wrongly rejecting the null hypothesis, $H_0$, if it is in fact true. This probability is always chosen by the investigators taking into account the consequences of such an error. That is, the significance level is kept low to reduce the chance of inadvertently making a false claim. The significance level, denoted by $\alpha$, is usually chosen to be 0.05 (5%). The corresponding $Z_{\alpha/2}$ is called the critical value of the $Z$ test. The critical value for a hypothesis test is a threshold with which the value of the test statistic calculated from a sample is compared in order to determine the $P$ value to be introduced next. For example, if $\alpha = 0.05$, we have $Z_{0.05/2} = 1.96$; if $\alpha = 0.01$, we have $Z_{0.01/2} = 2.58$.

A $P$ value is the probability of our result ($Z = 2.24$ for the SBP data) or a more extreme result ($Z < -2.24$ or $Z > 2.24$) being observed, assuming that the null hypothesis is true. The exact $P$ value in the $Z$ test is the probability of $Z \leq -Z_{\alpha/2}$ or $Z \geq Z_{\alpha/2}$, which can always be determined by calculating the area under the curve in two-sided symmetric tails from a statistical table specifically of a normal distribution [7, 14]. For the SBP data, the exact $P$ value = 0.025.

In a practical application, we often need to determine whether the $P$ value is smaller than a specified significance level, $\alpha$. This is performed by comparing the value of the test statistic with the critical value. Statistically $P \leq \alpha$ if, and only if, $Z = -Z_{\alpha/2}$ or $Z = Z_{\alpha/2}$. For the SBP data, since $Z = 2.24 > Z_{0.05/2} = 1.96$, we can conclude that $P < 0.05$. A smaller $P$ value indicates that $Z$ is further away from the center (i.e., the null value $\mu - \mu_0 = 0$) and consequently provides stronger evidence to support the alternative hypothesis of a difference.

Although the $P$ value measures the strength of evidence for a difference, which is largely dependent on the sample size, it does not provide the size and direction of that difference. Therefore, in a statistical report, $P$ values should be provided together with CIs (described in detail later) for the main outcomes [7, 14].

We are now in a position to interpret the $P$ value in relation to our data and decide whether there is sufficient evidence to reject the null hypothesis. Essentially, if $P = \alpha$, the prespecified significance level, then there is evidence against the null hypothesis, and we accept the alternative hypothesis stating that there is a statistically significant difference. The smaller the $P$ value, the lower the chance of obtaining a difference as big as the one observed if the null hypothesis were true, and, therefore, the stronger the evidence against the null hypothesis. Otherwise, if $P > \alpha$, there is not sufficient evidence to reject the null hypothesis or there is no statistically significant difference.

For our SBP data, since $P < 0.05$, we can state that there is evidence to reject the null hypothesis of no difference at the 5% significance level, and, therefore, that the mean SBP for the adult male population is statistically significantly different from 129 mmHg. Furthermore, the actual $P$ value equals 0.025, which suggests that the probability of falsely rejecting the null hypothesis is 1 in 40 if the null hypothesis is indeed true. On the other hand, $Z_{0.005} = 2.58 > Z = 2.24$, and $P$ is >0.01. Now we can state that there is no evidence to reject the null hypothesis of no difference if the significance level $\alpha$ is chosen as 0.01.

The implementation of the above procedures for hypothesis testing with the SBP data is summarized in Table 1.

### 4.2 Alpha (Type I) and Beta (Type II) Errors

When testing a hypothesis, two types of errors can occur. To explain these two types of errors, we will use the example of a randomized, double-blind, placebo-controlled clinical trial on a cholesterol-lowering drug A in middle-aged men and women considered to be at high risk for a heart attack. The primary endpoint is the reduction in the total cholesterol level at 6 months from randomization.

The null hypothesis is that there is no difference in mean cholesterol reduction level at 6 months postdose between patients receiving drug A ($\mu_1$) and patients receiving a placebo ($\mu_2$) ($H_0$: $\mu_1 = \mu_2$); the alternative hypothesis is that there is a difference ($H_a$: $\mu_1 \neq \mu_2$). If the null hypothesis is rejected when it is in fact true, then

**TABLE 1 Practical Procedures for Hypothesis Testing**

| Step | Procedure | Illustration with SBP[a] Data |
|---|---|---|
| 1 | Set up a null hypothesis and alternative hypothesis that is of particular interest to study. | $H_0$: $\mu = \mu_0$ (= 129), i.e., population mean SBP is equal to 129 mmHg<br>$H_a$: $\mu \neq \mu_0$, i.e., population mean SBP is different from 129 mmHg |
| 2 | Choose a statistical method according to data type and distribution and calculate its test statistic from the data collected. | $Z = \dfrac{\bar{X} - \mu_0}{S/\sqrt{n}} = 2.24$<br>$\bar{X} = 130$ mmHg<br>$S = 10$ mmHg<br>$n = 500$ |
| 3 | Define a significance level $\alpha$ and its corresponding critical value. | $\alpha = 0.05$ and $Z_{\alpha/2} = 1.96$<br>$\alpha = 0.01$ and $Z_{\alpha/2} = 2.58$ |
| 4 | Determine the $P$ value by comparing the test statistic and the critical value, or calculate the exact $P$ value. | Since $Z = 2.24 > 1.96$, $P < 0.05$<br>Since $Z = 2.24 < 2.58$, $P > 0.01$<br>Exact $P$ value = 0.025 |
| 5 | Make your conclusion according to the $P$ value. | As $0.01 < P < 0.05$, there is evidence to reject the null hypothesis of no difference at the 5% level of significance, but there is no evidence to reject the null hypothesis at the 1% level. The $P$ value of 0.025 means that the probability of falsely rejecting the null hypothesis is 1 in 40 if the null hypothesis is true |

[a]SBP, systolic blood pressure.

a type I error (or false-positive result) occurs. For example, a type I error is made if the trial result suggests that drug A reduced cholesterol levels when in fact there is no difference between drug A and placebo. The chosen probability of committing a type I error is known as the significance level [7, 12–14]. As discussed above, the level of significance is denoted by $\alpha$. In practice, $\alpha$ represents the consumer's risk [2], which is often chosen to be 5% (1 in 20).

On the other hand, if the null hypothesis is not rejected when it is actually false, then a type II error (or false-negative result) occurs [7, 12–14]. For example, a type II error is made if the trial result suggests that there is no difference between drug A and placebo in lowering the cholesterol level when in fact drug A does reduce the total cholesterol. The probability of committing a type II error, denoted by $\beta$, is sometimes referred to as the manufacturer's risk [2]. The power of the test is given by $1 - \beta$, representing the probability of correctly rejecting the null hypothesis when it is in fact false. It relates to detecting a prespecified difference.

### 4.3 Confidence Intervals

The second strategy for making statistical inference is through the use of CIs. In making inference about a population, we might want to know the likely value of the unknown population parameter [e.g., mean ($\mu$), proportion]. This is estimated from the sample statistics. For example, mean ($\bar{X}$), and we call $\bar{X}$ a point estimate of $\mu$.

In addition, we might want to provide some measure of our uncertainty as to how close the sample mean is to the true mean. This is done by calculating a CI (or interval estimate)—a range of values that has a specified probability of containing the true population parameter being estimated. For example, a 95% CI for the mean is usually interpreted as a range of values containing the true population mean with a probability of 0.95 [2]. The formula for the $(1-\alpha)\%$ CI around the sample mean ($\bar{X}$) corresponding to the $Z$ test, is given by

$$\bar{X} \pm Z_{\alpha/2}\mathrm{SE}(\bar{X})$$

where $\mathrm{SE}(\bar{X})$ is the standard error of $\bar{X}$, calculated by $S/\sqrt{n}$. This is a measure of the uncertainty of a single sample mean ($\bar{X}$) as an estimate of the population mean [7]. This uncertainty decreases as the sample size increases. The larger the sample size, the smaller the standard error. Therefore, the narrower the interval, the more precise the point estimate.

For our SBP example, the 95% CI for the population mean ($\mu$) can be calculated with the following formula:

$$\bar{X} \pm 1.96S/\sqrt{n} = 129.1\text{–}130.9\,\mathrm{mmHg}$$

This means that the interval between 129.1 and 130.9 mmHg has a 0.95 probability of containing the population mean $\mu$. In other words, we are 95% confident that the true population mean is between 129.1 and 130.9 mmHg, with the best estimate being 130 mmHg.

Confidence intervals can be calculated not just for a mean but also for any estimated parameter depending on the data types and statistical methods used [12, 14]. For example, one could estimate the proportion of people who smoke in a population, or the difference between the mean SBP in subjects taking an antihypertensive drug and those taking a placebo.

### 4.4 Relationship between Significant Testing and Confidence Intervals

When comparing, for example, two treatments, the purpose of significance testing is to assess the evidence for a difference in some outcome between the two groups, while the CI provides a range of values around the estimated treatment effect within which the unknown population parameter is expected to be with a given level of confidence.

There is a close relationship between the results of significance testing and CIs. This can be illustrated using the previously described $Z$ test for the SBP data analysis. If $H_0$: $\mu = \mu_0$ is rejected at the $\alpha\%$ significance level, the corresponding $(1-\alpha)\%$ CI will not include $\mu_0$. On the other hand, if $H_0$: $\mu = \mu_0$ is not rejected at the $\alpha\%$ significance level, then $(1-\alpha)\%$ CI will include $\mu_0$.

For the SBP data of adult males, the significance test shows that $\mu$ is significantly different from $\mu_0$ (= 129 mmHg) at the 5% level, and the 95% CI (= 129.1–130.9 mmHg) did not include 129 mmHg. On the other hand, the difference between $\mu$ and $\mu_0$ is not significant at the 1% level; the 99% CI $[129 \pm (2.58 \times 10)/\sqrt{500} = 128.8\text{–}131.2\,\mathrm{mmHg}]$ for $\mu$ does indeed contain $\mu_0$. Further information about the proper use of the above two statistical methods can be found in [7, 16].

### 4.5 Examples

Let us assume that four randomized, double-blind, placebo-controlled trials are conducted to establish the efficacy of two weight loss drugs (A and B) against placebo, with all subjects, whether on a drug or placebo, receiving similar instructions as to diet, exercise, behavior modification, and other lifestyle changes. The primary endpoint is the weight change (in kilograms) at 2 months from baseline. The difference in the mean weight change between an active drug and placebo groups can be considered as weight reduction for the active drug against placebo. Table 2 presents the results of hypothesis tests and CIs for the four hypothetical trials. The null hypothesis for each trial is that there is no difference between the active drug treatment and placebo in mean weight change. In trial 1 of drug A, the reduction of drug A over placebo was 6 kg with only 40 subjects in each group. The *P* value of 0.074 suggests that there is no evidence against the null hypothesis of no effect of drug A at the 5% significance level. The 95% CI shows that the results of the trial are consistent with a difference ranging from a large reduction of 12.6 kg in favor of drug A to a reduction of 0.6 kg in favor of placebo.

The results for trial 2 among 400 patients, again for drug A, suggest that mean weight was again reduced by 6 kg. This trial was much larger, and the *P* value ($P < 0.001$) shows strong evidence against the null hypothesis of no drug effect. The 95% CI suggests that the effect of drug A is a greater reduction in mean weight over placebo of between 3.9 and 8.1 kg. Because this trial was large, the 95% CI was narrow and the treatment effect was therefore measured more precisely. In trial 3, for drug B, the reduction in weight was 4 kg. Since the *P* value was 0.233, there was no evidence against the null hypothesis that drug B has no statistically significant benefit effect over placebo. Again this was a small trial with a wide 95% CI, ranging from a reduction of 10.6 kg to an increase of 2.6 kg for the drug B against the placebo.

The fourth trial on drug B was a large trial in which a relatively small, 2-kg reduction in mean weight was observed in the active treatment group compared with the placebo group. The *P* value (0.008) suggests that there is strong evidence against the null hypothesis of no drug effect. However, the 95% CI shows that the reduction is as little as 0.5 kg and as high as 3.5 kg. Even though this is convincing statistically, any recommendation for its use should consider the small reduction achieved alongside other benefits, disadvantages, and cost of this treatment.

Key points from the four trials are summarized in Table 3.

**TABLE 2 Point Estimate and 95% Confidence Interval (CI) for Difference in Mean Weight Change from Baseline between the Active Drug and Placebo Groups in Four Hypothetical Trials of Two Weight Reduction Drugs**

| Trial | Drug | No. of Patients per Group | Difference in Mean Weight Change from Baseline (kg) between the Active Drug and Placebo Groups | Standard Deviation of Difference | Standard Error of Difference | 95% CI for Difference | *P* value |
|---|---|---|---|---|---|---|---|
| 1 | A | 40 | –6 | 15 | 3.4 | –12.6, 0.6 | 0.074 |
| 2 | A | 400 | –6 | 15 | 1.1 | –8.1, –3.9 | <0.001 |
| 3 | B | 40 | –4 | 15 | 3.4 | –10.6, 2.6 | 0.233 |
| 4 | B | 800 | –2 | 15 | 0.8 | –3.5, –0.5 | 0.008 |

**TABLE 3 Summary of Key Points from Results Described in Table 2**

| Key Points from Significance Test and CI | Examples |
|---|---|
| In a small study, a large *P* value does not mean that the null hypothesis is true—absence of evidence is not evidence of absence | Trials 1 and 3 |
| A large study has a better chance of detecting a given treatment effect than a small study and is therefore more powerful | Trials 2 and 4 |
| A small study usually produces a CI for the treatment effect that is too wide to allow any useful conclusion | Trials 1 and 3 |
| A large study usually produces a narrow CI, and therefore a precise estimate of treatment effect | Trials 2 and 4 |
| The smaller the *P* value, the lower the chance of falsely rejecting the null hypothesis, and the stronger the evidence for rejecting the null hypothesis | Trials 2 and 4 |
| Even if the *P* value shows a statistically significant result, it does not mean that the treatment effect is clinically significant. The clinical importance of the estimated effects should always be assessed | Trial 4 |

## 5 COMPARISON OF TWO MEANS

The statistical methods used to compare two means of different treatment groups depend on how the two means were obtained. Data may be obtained from paired or unpaired samples. Paired samples occur when the source of the observations in the first sample are from the same source as the observations of a second or repeat sample. For quantitative data this means that repeated observations are from the same person using a before and after treatment method. Unpaired samples occur when individual observations in one group are independent of individual observations in the other. That is to say that the groups of subjects are different.

The most commonly used statistical test for the comparison of two means is the *t test*. The *t* test compares the means of two sets of continuous variables and expresses the probability that any differences are due to the play of chance (i.e., the null hypothesis is supported), or that the differences may be "real" (i.e., the alternative hypothesis is supported). This probability is often determined by a *t* value. The *t* tests can be used to compare two sample means for both paired and unpaired data, but formulas for calculating *t* values are different [12, 14]. An example of a *t* test for unpaired data is shown in Table 4.

From Table 4, we see that the *t* value of 2.055 corresponds to an observed *P* value of 0.040. The *P* value is the probability of observing the difference (3.440) or even larger (e.g., absolute difference >3.440) from the samples if the null hypothesis were true. The null hypothesis is that the difference in means of the two populations is zero. If there were no difference in systolic blood pressure between two treatment groups, there would be a small chance ($P = 0.040$) that we would observe the difference we did. We can turn this around and say that it is more likely that the two treatment groups differ. We say: "The difference in means between two treatment groups is statistically significant" since the observed *P* value is lower than our significance threshold value of $P = 0.05$.

The *t* test can be performed equivalently by calculating a confidence interval for the difference in means. A confidence interval is a range of values within which the "true" population parameter (such as difference in two means) is likely to lie. Usually 95% confidence limits are quoted, which implies that there is 95%

**TABLE 4 Example of Comparison of Two Means from Independent Samples—*t* Test**

An example calculation in a study to evaluate the effects of a treatment to reduce blood pressure are given. A randomized placebo-controlled trial comparing the effect of an antihypertensive therapy against placebo was conducted. The primary endpoint is systolic blood pressure at 6 months after randomization. The results of the two groups of patients were as follows:

Results of Blood Pressures

- In the control group of 548 patients the mean systolic blood pressure was 150.22 with a standard deviation of 27.12 mmHg
- In the treatment group of 550 patients the mean systolic blood pressure was 146.78 with a standard deviation of 28.32 mmHg

Using these data the *t* test can be calculated in the following manner:

Suppose two populations of sizes $n_1$ and $n_2$ have blood pressure results forming normal distributions with means $\bar{X}_1$ and $\bar{X}_2$ and standard deviations $S_1$ and $S_2$, respectively. Then the efficacy of the treatment, as compared to placebo, can be examined by testing the following hypotheses:

$$H_0 : \mu_1 = \mu_2$$

$$H_1 : \mu_1 \neq \mu_2$$

The statistic ($t$) for the above test is given by

$$t = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{\frac{[(n_1-1)S_1^2 + (n_2-1)S_2^2]}{(n_1+n_2-2)}}\sqrt{1/n_1 + 1/n_2}}$$

Therefore the null hypothesis can be rejected ($H_0$: $\mu_1 = \mu_2$) at the $\alpha$ level of significance if $|t| \geq t(\alpha/2, n_1 + n_2 - 2)$, where $t(\alpha/2, n_1 + n_2 - 2)$ is the upper ($\alpha/2$)th percentile of the $t$ distribution with $n_1 + n_2 - 2$ degrees of freedom.

In this case, we have $n_1 = 548$, $n_2 = 550$, $\bar{X}_1 = 150.22$, $\bar{X}_2 = 146.78$, $S_1 = 27.12$, $S_2 = 28.32$. Substituting the above sample statistics into the $t$-test formula, we obtain $t = 2.055$, which equates to a probability of 0.040 that the two populations are the same. The estimated difference in means together with its 95% confidence interval is 3.440 [0.156, 6.724].

As $P = 0.040 < 0.05$ (or 95% confidence interval does not contain 0), we can say that there is a statistically significant difference in the systolic blood pressures between the two treatment groups. In other words, the drug appears to reduce systolic blood pressure compared to placebo, and the result has a low likelihood of arising by chance.

confidence in the statement that the "true" population parameter will lie somewhere between the upper and lower limits. For the Table 4 data, the estimated 95% confidence interval for the difference in means is [0.156, 6.724]. If the 95% confidence interval does not contain zero, we can say that there is a statistically significant difference in means between two populations. For Table 4 data, as the lower limit of the 95% confidence interval is greater than zero, we can say that two means are statistically significantly different.

Four key assumptions are required in the two-sample $t$ test. Firstly, we assume that the two treatment group populations from which the samples are drawn are distributed normally [8, 12, 14]. Second, we assume that the variances (or standard deviations) of the two populations are equal [8, 12, 14], that is, $\sigma_1^2 = \sigma_2^2 = \sigma^2$. The equality of variances assumption can be formally verified with an $F$ test [8, 12, 14]. We can also perform an informal check by examining the relative magnitude of the two-sample variances $S_1^2$ and $S_2^2$. For example, if $S_1^2$ / $S_2^2$ is considerably different

from 1, then the assumption that $\sigma_1^2 = \sigma_2^2 = \sigma^2$ will be in doubt. In cases where $\sigma_1^2 \neq \sigma_2^2$, we need to use a modified *t* test or nonparametric method [8, 12, 14, 17]. Third, we assume that the observations in the two treatment groups are independent of each other, that is, no observation in one group is influenced by another observation in the second group [8, 12, 14, 17]. In other words, the value in one treatment group is not affected by that in another group. Finally, we assume that the two populations are homogeneous in terms of the observed and unobserved characteristics of patients (i.e., free from confounding) [7]. These characteristics might be demographics (such as age), prognosis (such as clinical history or disease severity), or baseline measurements of outcome variables.

Although we might never know the unobservable heterogeneity (differences) between two populations, we can assess whether the two populations are comparable by examining the observed summary statistics, such as means or proportions at baseline by treatment. This is why a table that summarizes the baseline information in a clinical trial by treatment group is always provided in a clinical report. If the two treatment groups are not balanced with regard to some of the predictors of outcome, covariate adjustment by means of stratification or regression modeling can be employed [1, 14, 17].

## 6 COMPARISON OF TWO PROPORTIONS

Quite often, we have a binary variable result or proportion to analyze from both groups. For example, in a clinical trial comparing a new treatment to reduce mortality after myocardial infarction, the primary endpoint is a binary outcome of death or survival. The numbers of subjects who die or survive in each of the two treatment groups form a $2 \times 2$ contingency table, from which we can calculate the rate of death or proportion dead for each treatment group [9, 12, 14].

The most common approaches for comparing two proportions are the chi-squared ($\chi^2$) test and the Fisher exact test. The $\chi^2$ test involves determining the expected number of deaths in the new and standard treatment arms and then comparing these to those observed numbers. The test statistic used to assess these differences in deaths can be expressed as $\chi^2 = \Sigma(O - E)^2/E$, where $O$ represents the observed frequencies and $E$ the expected frequencies in each cell of the $2 \times 2$ table. Under the null hypothesis, $\chi^2$ should follow a chi-squared distribution with one degree of freedom. The Fisher exact test is a little more complex and consists of evaluating the sum of probabilities associated with the observed frequency table and all possible two-by-two tables that have the same row and column totals as the observed data [9, 12, 14]. The $\chi^2$ test can also be used to compare more than two proportions [9, 12, 14].

When the total study size is large (say over 200), a test for the difference between two proportions also uses a normally distributed test statistic $Z$ (known as $Z$ test), which can be easily calculated by hand (Table 5).

The null hypothesis in Table 5 is that there is no difference between the two treatment groups in the death rate among patients after myocardial infarction. The $P$ value (<0.001) gives us the probability of observing the difference seen in the death rates (–0.028) if the null hypothesis were true. As the $P$ value is far less than 0.001, we can reject the null hypothesis and say that the difference in proportions is statistically significant.

**TABLE 5 Example of Comparison of Two Proportions—*Z* test**

A randomized placebo-controlled clinical trial was conducted to evaluate a cardiovascular drug on reducing mortality on patients with myocardial infarction (MI). The primary endpoint was the death after MI at 30 days after randomization. Following data were obtained from the trial:

- Group 1 (treatment) 110 deaths out of a total of 2045 patients
- Group 2 (placebo) 165 deaths out of a total of 2022 patients

Statistical inference of binary data such as death from parallel two-group trial involves testing the hypotheses regarding the difference in proportions with a yes response between the treatment and the placebo group. This can be expressed as

$$H_0 : \pi_1 = \pi_2$$

$$H_a : \pi_1 \neq \pi_2$$

The statistic for the above test is given by

$$Z = \frac{\hat{p}_1 - \hat{p}_2}{\sqrt{\hat{p}_c(1-\hat{p}_c)(1/n_1 + 1/n_2)}}$$

where $n_1$ and $n_2$ are the sample sizes (2045 and 2022), $X_1$ and $X_2$ the number of events in the two groups (110 and 165), respectively, and $\hat{p}_1 = X_1/n_1$ (= 110/2045 = 0.054), $\hat{p}_2 = X_2/n_2$ (= 165/2022 = 0.082), and $\hat{p}_c = (X_1 + X_2)/(n_1 + n_2)$ (= [(110 + 165)/(2045 + 2022)] = 0.068).

Therefore, the null hypothesis can be rejected ($H_0$: $\pi_1 = \pi_2$) at the $\alpha$ level of significance if $|Z| \geq Z_{\alpha/2}$, where $Z_{\alpha/2}$ is the upper ($\alpha$/2)th percentile of the standard normal distribution.

In this case the $Z = -3.548$, which equates to a probability of $P < 0.001$. The estimated difference is –0.028 (95% confidence interval: [–0.043, –0.012]).

The above results suggest that patients in the treatment group have a statistically significant lower death rate than patients in the placebo group.

Alternatively, we can calculate the confidence interval for the difference between the two rates. For the Table 5 data, the observed difference is –0.028 (–2.8%) with a 95% confidence interval [–4.3%, –1.2%]. From these results, we can say that there is a 95% probability that the difference that would be seen, if the entire population of all myocardial infarction patients were tested with either the new or standard treatment, would be between –4.3 and –1.2%. As the 95% confidence interval does not include zero, we can say that rate of death in the treatment group would be lower than that for standard treatment.

There is one common important assumption for the $\chi^2$ *t* test, the Fisher exact test, and the *Z* test: The two treatment groups are homogeneous in terms of the patients' characteristics (e.g., demographic information, disease-related risk factors, medical histories, and concurrent medical treatments). We can check whether the two groups are comparable by examining the observed baseline summary statistics. If the two treatment groups are not balanced with regard to some predictor(s) of outcome, logistic regression modeling could be used to adjust for these potential confounding factors [7, 9].

## 6.1 Assessing Size of Treatment Effect in Two-Arm Trial

In the previous sections, we have introduced different methods for assessing whether there is any evidence against the null hypothesis of no difference. In this section, we describe three commonly used measurements for assessing the size of any treatment effect for a binary outcome.

*Risk Difference* The difference in the proportion of the outcomes between two groups, $p_1 - p_2$, is called the risk difference. In the case of the myocardial infarction (MI) trial data, the risk difference is the risk of death between the active drug and placebo, that is, 5.4% – 8.2% = –2.8%. This means that the estimated absolute risk of death is 2.8% lower (about 3 in 100 MI patients) in the active drug group compared to the placebo group. Statistical inferences about the risk difference, such as point estimate and CIs, can be made by means of a $Z$ test, as described in the last section.

*Risk Ratio* The *risk ratio* is the ratio of the risks in the active drug treatment group compared to the placebo group. The risk ratio is often abbreviated to RR, and is also sometimes called the relative risk:

$$\mathrm{RR} = \frac{p_1}{p_2} = \frac{X_1/n_1}{X_2/n_2}$$

For the MI trial, the RR = 0.66 (5.4%/8.2%), meaning that the risk of death for the patients in the active drug treatment group is 66% of the risk in the placebo group. Equivalently, we could say that the drug treatment is associated with a 34% (100% – 66%) reduction in mortality at 30 days.

*Odds Ratio* A third measure of treatment effect is the *odds ratio* (OR). The odds of an outcome event are calculated as the number of events divided by the number of nonevents. For example, in the active treatment arm in the MI trial, the number of deaths is 110 and the number of survivals is 1935, so the odds of death are 110/1935 = 0.057. If the odds of an event are >1, the event is more likely to happen than not. In particular, the odds of an event that is certain to happen are infinite, and the odds of an impossible event are zero. The OR is calculated by dividing the odds in the active treatment group by the odds in the placebo group.
For the MI trial data, OR is calculated as $(110 \times 1857)/(1936 \times 165) = 0.64$, meaning that the odds of deaths after MI in the drug group is 64% of the odds in the placebo group. Clinical trials typically study treatments that reduce the proportion of patients with an event or equivalently have an OR < 1. In these cases, a percentage reduction in OR is often quoted instead of the OR itself. For the preceding OR, we can say that there is a 36% (100% – 64%) reduction in the odds of deaths in the active treatment group.

## 7 SURVIVAL ANALYSIS

In many clinical trials, the primary outcome is not just whether an event occurs but also the time it takes for the event to occur. For example, in a cancer study comparing the relative merits of surgery and chemotherapy treatments, the outcome measured could be the time from the start of therapy to the death of the subject. In this case the event of interest is death, but in other situations it might be the end of a period spent in remission from cancer spread, relief of symptoms, or a further admission to hospital. These types of data are generally referred to as time-to-event data or survival data even when the endpoint or the event being studied is something

other than the death of a subject. The term "survival analysis" encompasses the methods and models for analyzing such data representing time free of events of interest.

### 7.1 Example: Pancreatic Cancer Trial

The death rate from pancreatic cancer is among the highest of all cancers. A randomized controlled clinical trial was conducted on 36 patients diagnosed with pancreatic cancer. The aim of this trial was to assess whether the use of a new treatment (A) could increase the survival of patients compared to the standard treatment (B). Patients were followed-up for 48 months and the primary endpoint was the time, in months, from randomization to death. Table 6 displays the survival data for the 36 patients. We will use this example to illustrate some fundamental survival analysis methods and their applications.

### 7.2 Basic Concepts in Survival Analysis

*Censoring* In survival analysis, not all subjects are involved in the study for the same length of time due to *censoring*. This term denotes when information on the outcome status of a subject stops being available. This can be because the patient is lost to follow-up (e.g., they have moved away) or stops participating in the study, or because the end of study observation period is reached without the subject having an event. Censoring is a nearly universal feature of survival data. Table 7 summarizes

**TABLE 6 Survival Data for 36 Patients with Pancreatic Cancer in Trial of New Treatment versus Standard Treatment**

| New Treatment | | Standard Treatment | |
|---|---|---|---|
| Survival Time (months) | Survival Status (0 = survival, 1 = dead) | Survival Time (months) | Survival Status (0 = survival, 1 = dead) |
| 2 | 0 | 3 | 0 |
| 5 | 0 | 5 | 1 |
| 10 | 1 | 6 | 0 |
| 12 | 1 | 7 | 1 |
| 15 | 0 | 8 | 1 |
| 27 | 1 | 10 | 1 |
| 36 | 0 | 11 | 0 |
| 36 | 0 | 12 | 1 |
| 37 | 1 | 13 | 0 |
| 38 | 0 | 15 | 1 |
| 39 | 0 | 16 | 0 |
| 41 | 0 | 23 | 1 |
| 42 | 0 | 30 | 1 |
| 44 | 0 | 39 | 1 |
| 45 | 1 | 40 | 1 |
| 46 | 0 | 45 | 1 |
| 48 | 0 | 48 | 0 |
| 48 | 0 | 48 | 0 |

**TABLE 7 Reasons for Censoring Observations in Clinical Trials**

| Reason | Example |
|---|---|
| Lost to follow-up | Patient moved away or did not wish to continue participation. |
| Patient withdrawn | Patient withdraws from the study due to side effects. |
| Patient has an outcome that prevents the possibility of the primary endpoint (competing risk) | Death from cancer where death from cardiac causes is the primary endpoint. |
| Study termination | All patients who have not died are considered censored at the end of the study. |

the main reasons for censoring that can occur in a clinical trial. Survival analysis takes into account censored data, and, therefore, uses the information available from a clinical trial more fully.

*Survival Function and Hazard Function* In survival analysis, two functions are of central interest, namely *survival function* and *hazard function* [18, 19]. The survival function, $S(t)$, is the probability that the survival time of an individual is greater than or equal to time $t$. Since $S(t)$ is the probability of surviving (or remaining event-free) to time $t$, $1 - S(t)$ is the probability of experiencing an event by time $t$. Plotting a graph of probability against time produces a *survival curve*, which is a useful component in the analysis of such data.

The hazard function, $h(t)$, represents the instantaneous event rate at time $t$ for an individual surviving to time $t$ and, in the case of the pancreatic cancer trial, it represents the instantaneous death rate. With regard to numerical magnitude, the hazard is a quantity that has the form of "number of events per time unit" (or "per person-time unit" in an epidemiological study). For this reason, the hazard is sometimes interpreted as an incidence rate. To interpret the value of the hazard, we must know the unit in which time is measured.

For the pancreatic cancer trial, suppose that the hazard of death for a patient is 0.02, with time measured in months. This means that if the hazard remains constant over one month, then the death rate will be 0.02 deaths per month (or per person-months). In reality, the 36 patients contributed a total of 950 person-months and 16 deaths. Assuming that the hazard is constant over the 48-month period and across all patients, an estimate of the overall hazard is $16/950 = 0.017$ deaths per person-months.

*Kaplan–Meier Method* The Kaplan–Meier (KM) approach estimated the proportion of individuals surviving (i.e., who have not died or had an event) by any given time in the study [18, 19]. When there is no censoring in the survival data, the KM estimator is simple and intuitive. $S(t)$ is the probability that an event time is greater than $t$. Therefore, when no censoring occurs, the KM estimator, $\hat{S}(t)$, is the proportion of observations in the sample with event times greater than $t$. For example, if 50% of observations have times >10, we have $\hat{S}(10) = 0.50$.

The KM estimates of the survival curves by the two treatment groups for the pancreatic cancer trial data are displayed in Figure 2. The survival curve is shown in a step function: The curve is horizontal at all times at which there is no event, with a vertical drop corresponding to the change in the survival function at each time, $t_j$, when an event occurs.

In reports, KM curves are usually displayed in one of two ways. The curves can decrease with time from 1 (or 100%), denoting how many people survive (or remain event free). However, in general it is recommended that the increase in event rates is shown starting from 0 (or 0%) subjects, with an increasing curve $(1 - \hat{S}[t])$ unless the event rate is high [20]. Placing the curves for different treatment groups on the same graph allows us to graphically review any treatment differences.

*Log-Rank Test* For the two KM curves by treatment group shown in Figure 2, the obvious question to ask is: Did the new treatment make a difference in the survival experience of the two groups? A natural approach to answering this question is to test the null hypothesis that the survival function is the same in the two groups: that is, $H_0$: $S_1(t) = S_2(t)$ for all $t$, where 1 and 2 represent the new treatment and the standard treatment, respectively.

The above hypothesis can be assessed by performing a log-rank test equivalent to a $\chi^2$ test [18, 19, 21]. The main purpose of this test is to calculate the number of events expected in each treatment group, and to compare this expected number of events with the observed number of events in each treatment group if the null hypothesis is true.

For the pancreatic cancer trial, the resulting $\chi^2$ value is 5.424 [22], converted to a $P$ value of 0.020. As $P < 0.05$, the log-rank test has shown a significant survival difference between the new treatment A and standard treatment B. This test readily generalizes to three or more groups, with the null hypothesis that all groups have the same survival function. If the null hypothesis is true, the test statistic has a chi-

***FIGURE 2*** *Kaplan–Meier survival functions by treatment group for the pancreatic cancer trial data.*

squared distribution with the degrees of freedom equal to the number of groups minus 1.

*Cox Proportional-Hazards Model* The proportional-hazards model relates the hazard function to a number of covariates (such as patient's characteristics at randomization and the treatment received in a clinical trial) as follows [18, 19, 22]:

$$h_i(t) = h_0(t)\exp(b_1x_{1i} + b_2x_{2i} + K + b_px_{pi}) \tag{1}$$

where $x_{ki}$ is the value of the covariate $x_k$ $(k = 1, 2, \ldots, p)$ for an individual $i(i = 1, 2, \ldots, n)$.

The equation says that the hazard for individual $i$ at time $t$ is the product of two factors:

- A baseline hazard function $h_0(t)$ that is left unspecified, except that it cannot be negative.
- A linear function of a set of $p$ fixed covariates, which is then exponentiated.

The baseline hazard function can be regarded as the hazard function for an individual whose covariates all have values of 0 and changes according to time $t$.

This is called a proportional-hazards model because, while the baseline hazard can constantly change over time, the hazard for any individual is assumed to be proportional to the hazard for any other individual and will depend on the individual values of covariates. To see this, let us assume that the model only has one covariate (treatment, $x_{1i}$, $x_{1i} = 0$ for standard treatment and 1 for new treatment). We first calculate the hazards for two individuals 1 and 2 according the Equation (1) and then take the ratio of the two hazards:

$$\begin{aligned} h_1(t) &= h_0(t)\exp(b_1x_{11}) \\ h_2(t) &= h_0(t)\exp(b_1x_{12}) \\ \frac{h_1(t)}{h_2(t)} &= \exp[b_1(x_{11} - x_{12})] \end{aligned} \tag{2}$$

What is important about the equation is that $h_0(t)$ is canceled out of the numerator and denominator. As a result, the ratio of hazards, $\exp[b_1(x_{11} - x_{12})]$, is a constant over time or proportional.

### 7.3 Assessing Size of Treatment Effect in Two-Arm Trial for Survival Data

*Incidence Rate Difference and Ratio* The incidence rate is defined as the number of events divided by the number of units of time [14, 22]. By comparing the incidence rates between treatment groups, we can derive the incidence rate difference and ratios following the procedures described by Kirkwood and Sterne [14, 22]. For the pancreatic cancer trial data, the incidence rates are calculated as 0.9 and 2.9 deaths

per 100 person-months for the new treatment group and the standard treatment group, respectively. The estimates of incidence rate difference and rate ratio together with their 95% CI and $P$ value are as follows:

- Incidence rate difference: –2.0, 95% CI (–3.9, –0.1), $P = 0.034$
- Incidence rate ratio: 0.30, 95% CI (0.08, 0.94), $P = 0.026$

The above results suggest that the new treatment reduces deaths by 2 per 100 person-months, with a 95% CI of 0.1–3.9 per 100 person-months, and that the incidence rate for patients in the new treatment group is only about 30% of the incidence rate for those in the standard treatment group.

Although the incidence rate uses the information on censored observations, it is based on the assumption that the hazard of an event is constant during the study period or has an exponential distribution. In the case of the pancreatic cancer trial, it means that the hazard of death is constant over the 48-month period. However, the risk of an event can change with time. To overcome this problem, the Cox model, which does not require such assumptions, can be used to derive a better measurement for the treatment effect.

*Hazard Ratio* The treatment can be simply measured as a binary covariate (1 for new treatment A and 0 for standard treatment B in the pancreatic cancer trial) and introduced into a Cox proportional-hazards model. In the pancreatic cancer trial, the estimated hazard ratio of death for patients who received treatment A to those who received standard treatment B is 0.31, with 95% CI (0.11, 0.89), $P = 0.030$. This means that the new treatment is estimated to reduce the hazard of death by 69%, with 95% CI (11%, 89%) and the reduction in hazard is statistically significant at the 5% significance level. As there is only one covariate (treatment) in the Cox model, the estimated hazard ratio is called a crude or unadjusted treatment effect. The adjusted hazard ratio for the treatment will be generated if other baseline patient characteristics are introduced in the model.

## 8 COMMONLY USED TERMS IN CLINICAL TRIALS

***ANOVA (Analysis of Variance)*** A statistical method for comparing several means by comparing variances. It concerns a normally distributed outcome (response) variable and a single categorical (predictor) variable representing treatments or groups. ANOVA is a special case of a linear regression model by which group means can be easily compared.

***Bias*** Systematic errors associated with the inadequacies in the design, conduct, or analysis of a trial on the part of any of the participants of that trial (patients, medical personnel, trial coordinators, or researchers), or in publication of its the results, that make the estimate of a treatment effect deviate from its true value. Systematic errors are difficult to detect and cannot be analyzed statistically but can be reduced by using randomization, treatment concealment, blinding, and standardized study procedures.

***Confidence Intervals*** A range of values within which the "true" population parameter (e.g., mean, proportion, treatment effect) is likely to lie. Usually, 95% confidence limits are quoted, implying that there is 95% confidence in the statement that the "true" population parameter will lie somewhere between the lower and upper limits.

***Confounding*** A situation in which a variable (or factor) is related to both the study variable and the outcome so that the effect of the study variable on the outcome is distorted. For example, if a study found that coffee consumption (study variable) is associated with the risk of lung cancer (outcome), the confounding factor here would be cigarette smoking since coffee is often drunk while smoking a cigarette, which is the true risk factor for lung cancer. Thus, we can say that the apparent association of coffee drinking with lung cancer is due to confounding by cigarette smoking (confounding factor). In clinical trials, confounding occurs when a baseline characteristic (or variable) of patients is associated with the outcome, but unevenly distributed between treatment groups. As a result, the observed treatment difference from the unadjusted (univariate) analysis can be explained by the imbalanced distribution of this variable.

***Correlation Coefficient (r)*** A measure of the linear association between two continuous variables. The correlation coefficient varies between –1.0 and +1.0. The closer it is to 0, the weaker the association. When both variables go in the same direction (e.g., height and weight), $r$ has a positive value between 0 and 1.0 depending on the strength of the relationship. When the variables go in opposite directions (e.g., left ventricular function and life span), $r$ has a negative value between 0 and –1.0 depending on the strength of this inverse relationship.

***Covariates*** This term is generally used as an alternative to explanatory variables in regression analysis. However, more specifically refer to variables that are not of primary interest in an investigation. Covariates are often measured at baseline in clinical trials because it is believed that they are likely to affect the outcome variable and, consequently, need to be included to estimate the adjusted treatment effect.

***Descriptive/Inferential Statistics*** Descriptive statistics are used to summarize and describe data collected in a study. To summarize a quantitative (continuous) variable, measures of central location (i.e., mean, median, mode) and spread (e.g., range and standard deviation) are often used, whereas frequency distributions and percentages (proportions) are usually used to summarize a qualitative variable. Inferential statistics are used to make inferences or judgments about a larger population based on the data collected from a small sample drawn from the population. A key component of inferential statistics is hypothesis testing. Examples of inferential statistical methods are $t$ test and regression analysis.

***Endpoint*** Clearly defined outcome associated with an individual subject in a clinical research. Outcomes may be based on safety, efficacy, or other study objectives (e.g., pharmacokinetic parameters). An endpoint can be quantitative (e.g., systolic blood pressure, cell count), qualitative (e.g., death, severity of disease), or time to event (e.g., time to first hospitalization from randomization).

***Hazard Ratio*** In survival analysis, hazard (rate) represents instantaneous event rate (incidence rate) at a certain time for an individual who has not experienced an event at that time. Hazard ratio compares two hazards of having an event between two groups. If the hazard ratio is 2.0, then the hazard of having an event in one group is twice the hazard in the other group. The computation of the hazard ratio assumes that the ratio is consistent over time (proportional hazards assumption).

***Hypothesis Testing or Significance Testing*** Statistical procedure for assessing whether an observed treatment difference was due to random error (chance) by calculating a *P* value using the observed sample statistics such as mean, standard deviation, and so on. The *P* value is the probability that the observed data or more extreme data would have occurred if the null hypothesis (i.e., no true difference) were true. If the calculated *P* value is a small value (like <0.05), the null hypothesis is then rejected, and we state that there is a statistically significant difference.

***Intention-to-Treat Analysis*** A method of data analysis on the basis of the intention to treat a subject (i.e., the treatment regimen a patient was assigned at randomization) rather than the actual treatment regimen he or she received. It has the consequence that subjects allocated to a treatment group should be followed up, assessed, and analyzed as members of that group regardless of their compliance to that therapy or the protocol, irrespective of whether they later crossed over to the other treatment group or not or whether they discontinued treatment.

***Kaplan–Meier Estimate and Survival Curve*** A survival curve shows an estimate of the fraction of patients who survive over the follow-up period of the study without an event of interest (e.g., death). The Kaplan–Meier estimate is a simple way of computing the survival curve taking into account patients who were lost to follow-up or any other reasons for incomplete results (known as censored observations). It usually provides a staircase graph of the fraction of patients remaining free of event over time.

***Meta-Analysis*** The systematic review and evaluation of the evidence from two or more independent studies asking the same clinical question to yield an overall answer to the question.

***Normal Distribution*** A bell-shaped symmetric distribution for a continuous variable having highest frequency at a mean value and less frequency further away from this mean value. A normal distribution can be completely described by two parameters: mean ($\mu$) and variance ($\sigma^2$). In the special case of $\mu = 0$ and $\sigma^2 = 1$, it is called the standard normal distribution.

***Number Needed to Treat (NNT)*** This term is often used to describe how many patients would need to be given a treatment to prevent one event. It is determined from the absolute difference between one treatment and another. In a randomized study the group receiving treatment A had a death rate of 12.5%, and the group receiving treatment B had a death rate of 15.0%. Both groups are matched for size and length of follow-up. Comparing the two treatments there was an absolute risk reduction of 15% − 12.5% = 2.5% for treatment A. From this we can derive that the

NNT (= 1/0.025) is 40. This means 40 patients need to be given treatment A rather than B to prevent 1 additional death.

***Odds Ratio (OR) and Risk Ratio (RR)*** These terms compare the probability of having an event between two groups exposed to a risk factor or treatment. The RR is the ratio of the probability of occurrence of an event between two groups. The OR is the ratio of the ratio of patients with and without an event in each group. If the number of deaths in the treatment and control arms (both of sample size 100) of a randomized study are 50 and 25, respectively, the RR = (50/100) / (25/100) = 2. The treatment group has a twofold relative risk of dying compared with the control group. The OR = (50/50) / (25/75) = 3 indicates that the odds of death in the treatment arm is threefold of the control arm.

***Per-Protocol Analysis*** A method of analysis in which only the subset of subjects who complied sufficiently with the protocol are included. Protocol compliance includes exposure to treatment, availability of measurements, correct eligibility, and absence of any other major protocol violations. This approach contrasts with the more conservative and widely accepted "intention-to-treat" analysis.

***Power*** The probability of rejecting the null hypothesis (e.g., no treatment difference) when it is false. It is the basis of procedures for calculating the sample size required to detect an expected treatment effect of a particular magnitude.

***Random Error*** An unpredictable deviation of an observed value from a true value resulting from sampling variability. It is a reflection of the fact that the sample is smaller than the population; for larger samples, the random error is smaller, as opposed to systematic errors (bias) that keep adding up because they all go in the same direction.

***Regression Analyses*** Methods of explaining or predicting outcome variables using information from explanatory variables. Regression analyses are often used in clinical trials to estimate the adjusted treatment effect taking into account differences in baseline characteristics, and in epidemiological studies to identify prognostic factors while controlling for potential confounders. Commonly used regression models include linear, logistic, and Cox regression methods.

***Risk Factor*** A risk factor can be defined as anything in the environment, personal characteristics, or events that make it more or less likely one might develop a given disease, reach an adverse event or experience a change in health status. For example, raised cholesterol is a risk factor for heart attacks.

***Standard Error*** A measure of the random variability of a statistic (e.g., mean, proportion, treatment effect) indicating how far the statistic is likely to be from its true value. For example, standard error of the mean (SEM) indicates uncertainty of a single sample mean ($\bar{X}$) as an estimate of the population mean ($\mu$). A smaller SEM implies a more reliable estimate of the population mean. Standard error can be used to calculate confidence interval of an estimated population parameter. The

smaller the standard error, therefore, the narrower the confidence interval, and more precise the point estimate of the population parameter.

***Treatment Effect*** An effect attributed to a treatment in a clinical trial, often measured as the difference in a summary measure of an outcome variable between treatment groups. Commonly expressed as difference in means for a continuous outcome, a risk difference, risk ratio, or odds ratio for a binary outcome, and hazard ratio for a time-to-event outcome.

***Univariate/Multivariate Analysis*** The term variate refers to the term variable. A univariate analysis examines the association between a single variable and an outcome variable (correctly called a bivariate analysis), for example, age and occurrence of stroke. In a multivariate analysis, associations between many variables are examined simultaneously. In particular, multivariate regression analysis can be used to assess the relative importance and contribution of each predictor variable to the outcome variable. For example, a multivariate logistic regression can be undertaken to identify the most important prognostic factors among several risk factors (e.g., age, sex, systolic blood pressure, and cholesterol level) that predict the occurrence of stroke.

## 9 CONCLUDING REMARKS

We have introduced some basic statistical approaches to dealing with different types of data and samples. To apply these methods for data analysis, there are a few basic principles we should adhere to. We first need to make the purpose of the analysis clear. For example, is the analysis to compare groups or to estimate associations? Different purposes will require different methods. Second, we need to identify the nature of the data. Are they data from paired samples or two independent samples? Third, we need to examine the characteristics of the data. Are the variables qualitative or quantitative? Symmetrically distributed or not? These properties of the data will guide to use the correct assumptions for analysis. Important as the appropriate use of statistical methods is, we must also ensure that the data are clean, accurate, meaningful, and complete and were gathered reducing any biases occurring in the design, conduct, and analysis of the clinical trial. The advice of a statistician with experience in medical research should always be sought from the design through to completion and analysis phases of a clinical trial.

## 1 PRAGMATIC AND EXPLANATORY PERSPECTIVES

In 1967 Schwartz and Lellouch published an article in the *Journal of Chronic Diseases* (the precursor to the *Journal of Clinical Epidemiology*) titled "Explanatory and pragmatic attitudes in therapeutical trials" [1]. The article was significant because it clearly distinguished, for the first time, different philosophical attitudes of clinical trialists. Since that time the article has become a classic in the field of clinical trial methodology (the 2007 edition of *Web of Science* records 421 citations), and the ensuing discussion has stimulated development of several methodological advances.

Schwartz and Lellouch argued that clinical trialists can have explanatory or pragmatic attitudes (or perspectives, or orientations) to clinical trials. These attitudes influence many aspects of trial design. In the contemporary literature, explanatory trials may be called "efficacy trials" [2, 3]. Pragmatic trials may be called "effectiveness trials" [2, 3] or "practical clinical trials" [4] or, nearly synonymously, "large simple trials" [5].

Explanatory trialists conceive of clinical trials as being clinical analogs of classic laboratory experiments. The aim is to learn of the potential effects of the specific intervention. Explanatory trials are designed to establish "proof of concept" of a new intervention [3] (Table 1).

In contrast, pragmatic trialists think of clinical trials as a mechanism for informing clinical decisions. Pragmatic trials tell us about the importance of interventions in the real world of clinical practice. They are designed to inform clinical decisions about whether to implement a particular intervention.

We need both explanatory and pragmatic trials. It would appear sensible to first conduct explanatory trials on a particular intervention and then subsequently subject the same intervention to a pragmatic trial. An exception might be where health interventions become established clinical practice before they are subject to clinical trials. Arguably, the first trials of such interventions should adopt a pragmatic approach.

Trialists rarely make explicit statements, in trial reports, about whether their intentions are explanatory or pragmatic. Many trials incorporate some features of explanatory trials and some features of pragmatic trials. This suggests that at least some trialists do not clearly think through whether their intentions are explanatory or pragmatic.

**TABLE 1 Explanatory and Pragmatic Attitudes to Clinical Trials**

| Explanatory Attitudes | Pragmatic Attitudes |
|---|---|
| Aim is to learn about effects of an intervention. | Aim is to make a decision about whether to administer an intervention. |
| Interest is in any effect. | Interest is in clinically important effects. |
| Ascertains if an intervention *can* produce effects (proof of concept). | Ascertains if an intervention *does* confer effects. |
| Used to make inferences about specific effects of narrowly defined interventions given under optimal conditions. | Used to make inferences about the real-world effects of complex interventions in routine clinical practice. |

Those trialists who explicitly adopt a particular perspective may find themselves misunderstood by reviewers of grant applications or journals. Sometimes pragmatic trials are criticized for failing to satisfy requirements that are particular to explanatory trials and vice versa. Thus it appears that the issues raised by Schwartz and Lellouch over 40 years ago are still not fully appreciated by clinical trialists.

This chapter discusses some of the consequences of the trialist's perspective (explanatory or pragmatic) for design and analysis of randomized trials. The chapter concludes by making some recommendations for the design, analysis, and reporting of randomized trials.

## 2 PARTICIPANTS

### 2.1 Inclusion and Exclusion Criteria

One of the first issues that confront trialists, when developing a trial protocol, is which patients to include in the trial.

If the intention is to learn whether the intervention *could* be effective (the explanatory perspective), then a sensible course of action would be to recruit those patients in whom effects of intervention are most likely to be apparent. Usually, this involves sampling from a carefully selected and homogenous population. Careful formulation of inclusion and exclusion criteria can ensure that only participants with characteristics likely to be associated with large treatment effects are sampled, and homogeneous sampling can ensure that the variance of outcomes is minimized. Selective, homogenous sampling maximizes the possibility of detecting effects of intervention, but it may also exclude patients who might, in the course of normal clinical practice, be offered the intervention. People with comorbidities, pregnant women, and people who do not speak the local language are typically excluded from explanatory trials.

Pragmatic trialists seek to make inferences about the effects of an intervention on the population for whom the intervention is indicated. Thus pragmatic trials typically sample broadly. Typically, they have broad inclusion criteria and few exclusion criteria. (In some trials the primary inclusion criterion is simply that the relevant clinician might choose to offer the intervention and the participant might choose to accept it. An example of such a trial is the MRC Spinal Stabilisation Trial in which the primary inclusion criterion was that "patients who were candidates for surgical stabilisation of the spine were eligible if the clinician and patient were uncertain which of the study treatment strategies was best" [6].) Pragmatic trials often sample patients under the care of many clinicians and from multiple sites [4].

Ideally, pragmatic trials would do more than sample broadly. Theoretically, at least, pragmatic trials should sample in a representative way from the population about which inferences are to be made. Random sampling is usually difficult or impossible, so there are very few examples of trials that randomly sample participants. However, a small number of studies have made explicit attempts to sample as representatively as possible. Fransen and colleagues describe how they attempted to obtain a representative sample of general medical practitioners and patients in the DIAMOND study of two protocols for management of dyspepsia in primary care [7].

### 2.2 Run-In Periods

In some trials, patients are not randomized at the time they are recruited into the trial. Instead, they are asked to participate in a run-in period, during which their compliance with the intervention (or, more usually, with the placebo intervention) is monitored. Only those patients who demonstrate a sufficiently high level of compliance are subsequently randomized into the trial. Thus the run-in period serves to winnow out potential participants who are unlikely to comply with the intervention specified in the trial protocol.

The use of run-in periods offers several potential benefits to explanatory trialists. First, run-in periods can reduce loss to follow-up. Second, the use of a run-in period potentially increases compliance, enabling better explanatory estimates of effects of intervention (see Section 6). Third, simulation studies show that when there is both a high degree of noncompliance and the run-in period gives an accurate indication of who will and will not comply with the intervention protocol, the use of a run-in period can produce modest increases in statistical efficiency [8]. (That is, slightly fewer patients would need to be recruited to a trial with a run-in period to yield the same level of statistical power as a trial without a run-in period.) However, these benefits are not guaranteed: When compliance is high or the ability to discriminate between compliant and noncompliant patients is low, the statistical efficiency of trials with run-in periods may actually be lower than in trials without a run-in period [8]. Trials with run-in periods require a longer period of participation in the trial, which could paradoxically reduce participation rates and increase rates of noncompliance and loss to follow-up. Thus, while the use of run-in periods may seem attractive to explanatory trialists, they can be counterproductive.

The use of run-in periods is much less attractive to pragmatic trialists because pragmatists are much more tolerant of noncompliance. From the pragmatic perspective, noncompliance is as much a characteristic of the intervention as it is of the patient. If patients do not comply with an intervention, then the intervention is unlikely to be of any real practical effect, regardless of its explanatory effects. Insofar as a pragmatic estimate of the effect of an intervention depends on the degree of compliance with the intervention, a pragmatic trial of the intervention should involve patients with similar levels of compliance to the population about whom inferences are to be made. This means that, theoretically at least, pragmatic trialists should seek to recruit participants with representative levels of compliance. As discussed above, pragmatic trialists have rarely made explicit efforts to sample representatively, so it may be often true that pragmatic trials do not sample patients with representative levels of compliance.

## 3 SAMPLE SIZE

### 3.1 Criteria Used to Calculate Sample Size

The classic hypothesis testing approach to sample size calculation is to calculate the sample size required to provide adequate statistical power to detect an effect of intervention while keeping the probability of falsely claiming an effect to acceptably low levels.

A fairly general form of the equation for estimating sample size in two-armed clinical trials with equally sized groups is

$$n \geq 2\left(z_{1-\alpha/2} + z_{1-\beta}\right)^2 \left(\frac{\mathrm{SD}^2}{\delta^2}\right)$$

where $n$ is sample size per group, $z_{1-\alpha/2}$ is the $z$ score corresponding to the probability, $\alpha$, of falsely rejecting the null hypothesis, $z_{1-\beta}$ is the $z$ score corresponding to the probability, $\beta$, of falsely retaining the null hypothesis, SD is the within-group standard deviation (usually assumed to be the same for both groups), and $\delta$ is the smallest effect worth detecting [9].

This approach to sample size calculation is widely used but, because it is built on a hypothesis testing approach to statistical inference, and because hypothesis testing is becoming increasingly regarded with suspicion by methodologists, it has been strongly criticized (see, e.g., [10]). Here discussion of issues of sample size calculation is restricted to comparison of explanatory and pragmatic approaches to sample size calculation.

The explanatory trialist might wish to detect *any* effect of intervention, no matter how small. This is because the explanatory trialist's interest is in proof of concept rather than in whether the effect of intervention is large enough to make the intervention worth implementing in clinical practice. But it is not possible to design trials to reliably detect *any* effect because the sample sizes required to detect very small effects become impossibly large. The hypothesis testing approach requires the trialist to nominate $\delta$, the smallest effect that is worth knowing about, and calculate the sample size required to detect effects of at least that size. This is problematic for explanatory trialists because in explanatory trials the choice of $\delta$ seems arbitrary. Consequently, sample sizes calculated for explanatory trials seem arbitrary too.

Pragmatic trialists find the task of nominating $\delta$ more straightforward. Pragmatic trials are intended to inform decisions about whether or not to implement an intervention, so they should be designed to reliably detect effects of intervention that are just large enough to warrant the risks, costs, discomforts, and inconveniences of intervention [11, 12]. Recently, Barrett and colleagues have developed the benefit–harm trade-off method to establish patient-focused estimates of the smallest important effect of intervention [13–15]. This method can be used to obtain empirical estimates of $\delta$.

Paradoxically, while pragmatic trialists may find it easier to nominate $\delta$ than explanatory trialists, it has been argued that it is not necessary for pragmatic trialists to nominate $\delta$ [1, 16]. The argument is as follows. The pragmatic trialist does not care about falsely rejecting the null hypothesis because, from the pragmatic trialist's perspective, if the interventions given in the two arms of the trial are equally effective, it does not matter which of the two interventions is administered in clinical practice. Insofar as pragmatic trialists do not care about falsely rejecting the null hypothesis, they should always consider that the intervention with the larger observed effect is the more effective intervention, regardless of any considerations of sampling error. This strategy results in one of three possible scenarios:

1. The two interventions have identical effects, but the trialist claims one is more effective than the other.

2. One intervention is more effective than the other, and the trialist correctly identifies the more effective intervention.
3. One intervention is more effective than the other, and the trialist incorrectly concludes the less effective intervention is the more effective one.

According to Schwartz and Lellouch [1], only the last type of error is of any concern to the pragmatic trialist. They refer to the probability of this kind of error as $\gamma$. As the pragmatic trialist wishes only to minimize $\gamma$, such studies requires only a sample size of

$$n \geq 2\left(z_{1-\gamma}\right)^2\left(\frac{\mathrm{SD}^2}{\delta^2}\right)$$

Even if $\gamma$ is set at just 1%, the sample size calculated in this way will be nearly one-third less than with conventional calculations that assume $\alpha = 0.05$ and $\beta = 0.2$. This observation has been used to defend the conduct of small pragmatic trials [17].

As MacRae has pointed out, Schwartz and Lellouch's approach to sample size calculation for pragmatic trials should only be used when the trialist is prepared to apply an intervention that is no more effective than alternative interventions [16]. In practice, that is often not the case because competing interventions often have quite different risks, inconveniences, and costs. For example, most surgeons would be disinclined to offer spinal stabilization surgery to patients with chronic low back pain if alternatives such as an intensive rehabilitation program have similar effects because the surgery is associated with significantly greater risks, discomfort, inconvenience, and costs than rehabilitation [6].

From a pragmatic perspective, the hypothesis testing approach to sample size calculation is quite unsatisfactory. Pragmatic trials should be designed to assist clinicians and health policymakers make decisions about whether the effects of particular interventions are big enough to be worthwhile. The most useful trials are those that provide precise estimates of the effects of intervention: The more precise the estimate, the more likely it will be that the decision maker will be able to conclude that the intervention definitely is or is not worth implementing [11, 12]. In practice, the hypothesis testing approach to sample size calculation often yields estimates of treatment effects that are too imprecise to be useful for clinical decision making. (That is, confidence intervals or credible intervals are usually so broad that they include both clinically worthless and clinically worthwhile effects.) This suggests an alternative approach to sample size calculation is needed. A better approach may be to explicitly specify the precision required of estimates of effect, and then estimate the sample size required to achieve that precision [18]. Admittedly, the choice of the acceptable precision will usually be quite arbitrary.

### 3.2 An Even More Pragmatic Approach: Value of Information

One response to the issues outlined above is to use decision-theoretic approaches to sample size calculation. Decision-theoretic approaches are explicitly pragmatic because they seek to maximize the difference between the cost of a trial and the expected value of the results.

Willan and Pinto have described a decision theoretic approach to sample size calculation in clinical trials [19]. They take a societal perspective, although the broad approach could be modified to take other perspectives such as the perspective of a corporate entity. They estimate the expected value of a trial (the expected value of sample information), the cost of conducting the trial, and the opportunity cost of treating some patients in the trial with the inferior intervention. All three quantities (the value of sample information and the cost and opportunity costs of the trial) are functions of sample size. The optimal sample size is that which maximizes the value of the trial minus its costs. This approach will often result in radically different estimates of sample size to those obtained with traditional methods. Indeed Willan and Pinto show that in some circumstances optimal trial size is zero, and the intervention should be implemented without first conducting a randomized trial.

Willan and Pinto's [19] approach to sample size calculation is attractive because it is rational and because it does not require the trialist to go through the arbitrary exercise of nominating $\alpha$, $\beta$, and $\delta$. The disadvantage is that the calculations are complex and require that the trialist nominate other difficult-to-estimate quantities such as the number of patients who would, in the future, be eligible to receive the experimental or control interventions.

### 3.3 Adjusting Sample Size Calculations for Noncompliance

As noted above, explanatory trialists try to minimize noncompliance with intervention. From an explanatory trialist's perspective, participants who do not receive the experimental intervention cannot provide information about the effects of that intervention. In most trials, however, some degree of noncompliance is inevitable and explanatory trialists need to decide how to deal with it.

One strategy is to omit noncompliant cases in a "per protocol analysis." If the primary analysis is to be conducted per protocol (though it is not clear that it ever should—see Section 6), the sample size calculations should anticipate the loss of participants due to noncompliance and apply an appropriate correction. In the simplest scenario in which similar proportions of participants are randomly excluded from two equally sized groups, the sample size should be increased by a factor of 1/(1 – anticipated proportion excluded).

A better alternative is to retain all participants in the analysis and apply a correction for attenuation of the explanatory effect by noncompliance (see Section 6). If the primary analysis is to involve obtaining estimates of explanatory effects of intervention calculated in this way, then the sample size should be adjusted accordingly. Newcombe [20] describes a method for adjusting conventional sample size calculations when an explanatory effect of intervention is to be estimated from the difference between two means, and Sato [21] provides sample size formulas for trials in which the explanatory effect of intervention is to be estimated as a risk difference. Sommer and Zeger tabulate the relative efficiency of pragmatic and explanatory estimates of risk ratios [22].

As discussed in Section 2, pragmatic trialists consider that noncompliance is a nonissue. Pragmatic trialists are uninterested in the hypothetical effect that an intervention could have in the presence of complete compliance. To them the parameter of most interest is the average effect of the intervention in clinical populations. It is understood that clinical populations contain some patients who do not

comply with intervention. For this reason pragmatic trialists generally do not adjust sample size estimates for noncompliance.

## 4 INTERVENTIONS

### 4.1 Experimental Intervention

Some health interventions are constrained by tight protocols that ensure uniformity of clinical practice. More often clinical practice is highly variable. Many clinicians have quite a high degree of autonomy, and they tend to develop their own formal or informal protocols for administering particular interventions. Individual clinicians may develop idiosyncratic decision rules that are not shared by other clinicians. In some settings a particular intervention may be administered in a technically adept manner using optimal protocols by clinicians who appear competent and demonstrate empathy. In other settings the same intervention may be administered tardily, incompetently, or indifferently.

The explanatory trialist wants to know about the effects of an intervention when it is administered optimally. Consequently, explanatory trialists expend considerable effort ensuring that the intervention is administered as well as is possible. Usually, the intervention is administered by a clinician with recognized expertise, and the intervention is administered according to strict protocols. This confers an incidental advantage: It ensures that it is clear precisely what intervention has been provided in the trial, so there need be little ambiguity about precisely what sorts of intervention the trial can be used to make inferences about.

The pragmatic trialist's interest is, instead, in the effects of the intervention as it is administered in real practice. (Or, when the trial is of a *new* intervention, the pragmatic trialist's interest is in what the effects of the intervention *would be* if it was to be administered in real practice.) Seen from this perspective, there is no necessity to enforce optimal intervention in clinical trials other than with the usual mechanisms that regulate the quality of clinical care. The interventions should be applied by clinicians who are representative of the spectrum of clinicians who apply (or would apply) the intervention in clinical practice, not exclusively by expert clinicians.

Useful pragmatic estimates of the effects of an intervention may be difficult to obtain when the intervention is new and administration of the intervention is difficult. An important example is new surgical techniques. The problem arises because new surgical techniques are pioneered by surgeons who have specific expertise in that type of surgery, but with time those techniques come to be more widely used by surgeons with less specific expertise. Moreover, the techniques themselves usually evolve rapidly, so that over the months and years that follow the introduction of the technique the standard approach becomes refined. Pragmatic interest should be in the effects of the intervention some time after the introduction of the new technique, at a time when the intervention has become, or could have become, part of routine surgical practice. By that time the technique may have been greatly refined, many more surgeons (including those with less expertise in the field) may be using the technique, and good training programs may have been introduced. A trial conducted soon after the introduction of a new surgical technique might neces-

sarily involve sampling unusually gifted surgeons who are relatively unpracticed in the technique, and might involve the administration of relatively unrefined surgical methods, compared to the same trial conducted several years later. Thus, while it may be possible to conduct explanatory trials seeking proof of concept soon after the introduction of a new surgical technique, it may be impossible to obtain realistic and generalizable pragmatic estimates of effect until the surgical technique has become widely established. Only then may it become possible to observe the effects of surgeons with widely representative competence performing refined surgical techniques.

### 4.2 Comparison Intervention

The choice of comparison intervention should reflect the orientation of a trial. Explanatory trialists usually aim to determine the specific effects of an intervention. To them, nonspecific effects associated with the rituals of administration of the intervention and the interactions between the clinician and patient are usually of no interest and should not be allowed to contaminate estimates of the specific effects of the intervention. It is possible to estimate the specific effects of intervention by ensuring that both the experimental and control groups experience exactly the same nonspecific effects. That is, explanatory trialists can ensure that estimates of the effects of intervention are uncontaminated by nonspecific effects by ensuring that experimental and control interventions are "equalized" [1].

Experimental and control interventions can be equalized by providing a placebo (or sham) intervention to the control group. The ideal placebo intervention is one that involves identical nonspecific rituals of administration but lacks the specific effects of the experimental intervention. Thus most phase III drug trials compare the outcomes of a group of patients given pills (or injections, or ...) containing the experimental compound with the outcomes of a group given pills that are identical in shape, size, and color but that do not contain the experimental compound. Then both the experimental and control groups experience, on average, similar nonspecific effects associated with administration of the intervention. As a consequence, estimates of the effects of the intervention (the difference in the outcomes of the two groups) are believed to be uncontaminated by these nonspecific effects.

Similar reasoning is used to justify blinding of the clinician who administers the intervention. Blinding of the clinician ensures that, on average, the clinician provides the same degree of enthusiasm and positive regard when administering both interventions [2].

There is almost universal agreement that phase III drug trials should blind both the participants (patients) and the clinician administering the intervention. In contrast, there is much more ambivalence among researchers about blinding patients and clinicians in trials of other sorts of interventions. Trials of surgical interventions, medical devices, and programs of care such as educational interventions, exercise programs, and psychological or behavioural interventions frequently do not blind patients or clinicians. No doubt this is due, at least in part, to issues of feasibility: It can be difficult to design a sham intervention that is both comparable to the experimental intervention and therapeutically inert, ethical considerations may preclude the provision of a convincing sham, and it may be difficult to blind clinicians to whether they have administered the experimental or sham intervention. But there

are also theoretical objections to the use of sham interventions: Placebo controls are important in explanatory trials but may be unnecessary, or less necessary, in pragmatic trials.

To the pragmatic trialist, nonspecific effects are a potentially important component of the total effect of an intervention. Therefore, from the pragmatic trialist's perspective, there is no need to separately estimate specific and nonspecific effects. The pragmatic trialist needs only to know the total effect (the sum of nonspecific and specific effects) of administering the intervention. It is this effect that can be anticipated when the intervention is administered to patients in clinical practice. From this perspective there is no need to equalize exposure to nonspecific factors in experimental and control groups. Instead it is more important that the control group is offered a clinically relevant alternative intervention. In Schwartz and Lellouch's terminology, the goal of the pragmatic approach is to optimize rather than equalize the control intervention [1].

More generally, pragmatic trialists need to know whether their patients will experience better outcomes if prescribed the experimental intervention than if prescribed the best available alternative intervention. In general, then, pragmatic trials should compare outcomes of participants receiving the experimental intervention with the outcomes of participants receiving the best available alternative intervention. When the best alternative intervention is minimal intervention (such as advice and support), the most useful trial is one that compares the outcome of participants given the experimental intervention with the outcomes of participants that receives minimal intervention. When the best alternative intervention is a particular program of treatment, the most useful trial is one that compares the outcome of participants given the experimental intervention with the outcome of participants that receive that program of treatment. The principle is that pragmatic trialists should conduct trials with clinically reasonable (relevant) comparison groups [4]. For this reason pragmatic trialists should seriously consider *not* conducting placebo-controlled trials [23].

This advice needs to be qualified. First, the nonspecific effects of intervention may be context-specific. For example, it may be that a particular intervention has placebo effects that manifest in the context of a particular trial (where, e.g., there may be a particularly high degree of regard paid to the patient) but not in the context of broader clinical practice. Context-specific nonspecific effects are of little interest and should be controlled for. Also, the imperative to obtain clinically relevant comparisons may be outweighed by the need to prevent bias. In clinical trials, blinding of participants and clinicians serves additional purposes, over and above controlling for nonspecific effects associated with the rituals of administration of the intervention. At least theoretically, blinding could reduce differential loss to follow-up. More importantly, whenever outcomes are measured subjectively (as they often must be in pragmatic trials) blinding of participants prevents any possibility that the effects of treatment are biased by participants anticipating the responses that they believe the researchers want to hear (the "polite-patient effect" [12]). One of the greatest advantages of blinding of assessors in trials is that it means subjective outcomes can be evaluated without fear of assessor bias ("the clinical impression can be included and given full weight in the analysis" [24]). These important considerations may cause even the most pragmatic trialist to implement placebo controls in their trials.

## 5 CHOICE OF OUTCOMES

Unlike pragmatic trialists, explanatory trialists are not preoccupied with the issue of whether the effects of intervention justify adoption of the intervention in clinical practice; they simply want proof of the concept that the intervention produces certain specific effects. Thus explanatory trialists often use measures of disease activity or disease severity as the primary trial outcomes or endpoints. Examples include measures of tumor size, blood pressure, biochemical markers, muscle strength, bone density, and so on.

In the clinical trials literature these sorts of outcomes are often called surrogate outcomes [25, 26]. Trials that monitor surrogate outcomes are generally considered to be less useful than trials that monitor clinical outcomes such as mortality or quality of life because, as history has shown, surrogate outcomes can provide a misleading indication of the true clinical effects of intervention on mortality or quality of life [26].

The contemporary suspicion of surrogate outcomes is underpinned by two very pragmatic ideas. First, pragmatic decisions about whether or not to implement an intervention involve weighing up all of the potential good and all of the potential harm caused by the intervention. This is more easily achieved by examining global measures of benefit and harm than by assessing the effects of the intervention on specific measures of disease activity. Second, an intervention is ultimately only of clinical benefit if it increases length of life or quality of life. For this reason, the primary outcomes of pragmatic trials should be measures of mortality (survival) or quality of life.

The assessment of mortality is relatively straightforward. A minor controversy concerns which deaths should be counted. Explanatory trialists may prefer to measure disease-specific mortality because analyses of disease-specific mortality may have more statistical power, and therefore be more able to detect effects of intervention, than analyses of all-cause mortality [27]. Pragmatic trialists are more inclined to count all deaths, regardless of their cause, rather than disease-specific mortality. All-cause mortality provides a more global measure of the effects of an intervention because it allows for the possibility that reductions in disease-specific mortality are offset by increases in other causes of mortality [28].

Measurement of quality of life is a more complex task. Quality of life can be measured with generic scales or with any of numerous disease-specific quality-of-life measures [29]. Some trialists are reluctant to measure quality of life because they believe measures of quality of life are relatively insensitive to change and may obscure real effects of intervention. But such reluctance may not always be justified. The *measure* of quality of life must be sensitive to changes in the underlying construct (the latent variable of true quality of life) but, at least from a pragmatic perspective, there need not be any requirement that the underlying construct of quality of life should be sensitive to change.

Outcome measures can be considered to lie on a spectrum. At the explanatory end are measures of disease activity, like biochemistry results, and at the pragmatic end are mortality and quality of life. Somewhere between the ends of this spectrum are outcome measures that are not formal measures of quality of life but could reasonably be expected to reflect quality of life. Examples include measures of depression, or disability, or incidence of injury, or severity of incontinence. From an

extremely pragmatic perspective these measures are really only of interest insofar as they can be used to predict quality of life or costs. Nonetheless, because it is reasonable to expect that these sorts of outcomes are likely to be important determinants of quality of life, they may provide suitable endpoints for pragmatic trials.

Policy-level decisions about whether to implement a particular intervention should be informed by cost-effectiveness (or cost-utility) analyses. For this reason pragmatic trials often measure costs of intervention. Costs to the consumer and health service providers can usually be quantified with relatively little difficulty, although costs to society may be considerably more difficult to estimate. Cost-effectiveness and cost-utility analyses are naturally pragmatic in their orientation so they should always be based on pragmatic outcomes such as quality of life.

## 6 ANALYSIS

### 6.1 Who Should Be Included in Analysis?

Even the best conducted trials experience protocol violations. For example, participants in the experimental group may fail to be given, or comply with, the experimental intervention. Participants in the control group may fail to comply with the control intervention. Participants in either group may be given co-interventions other than those specified in the protocol. People who do not satisfy the inclusion criteria may be incorrectly admitted to the trial. Outcome measures may be obtained at times other than (usually later than) specified in the protocol.

Some trialists may be tempted to identify participants who experience serious protocol violations and exclude those participants' data from the analysis (a per protocol analysis). This strategy might be particularly attractive to explanatory trialists because it might appear that excluding noncompliant participants' data from the analysis would provide a better estimate of the effect of intervention in compliant participants. However, per protocol analyses are potentially seriously biased [30]. Insofar as protocol violations are related to allocation, exclusion of randomized participants can produce imbalance in observed or unobserved baseline covariates. The potential for bias is great when the proportion of excluded participants is moderate or large. In addition, because per protocol analyses are conducted on a subsample of data, they may be underpowered. Another problem is that inference in per protocol analyses is to a relatively poorly and retrospectively defined population.

For these reasons the primary analysis of most clinical trials should be conducted on all available data from all randomized patients. More generally, the analysis should be conducted on an "intention-to-treat" basis. Different meanings are ascribed to the term intention to treat [31], but here the term is used to mean that (a) wherever possible outcome data are obtained from all trial participants (i.e., from every person who was randomized, not just those for whom the trial protocol was followed), (b) all available data (not just data from participants for whom the protocol was followed) are included in analysis, and (c) each participant's data are analyzed in the groups to which the participant was assigned (not according to treatment actually received). In short, the intention-to-treat policy is one of "ever randomised, always analysed" [32].

There may be some circumstances under which departures from an intention-to-treat policy may be reasonable. Fergusson and colleagues [33] have argued that it is reasonable to exclude from the analysis those participants who were clearly ineligible to participate in the trial at the time they were randomized (i.e., people whose inclusion in the trial was a result of the researchers' failure to follow the protocol). On the other hand, participants should not be excluded from the analysis if the information required to determine they did not meet eligibility criteria only became apparent sometime after randomization. For example, participants who were thought to have a particular diagnosis, but who were found some time after randomization to have an alternative diagnosis that would have excluded them from the trial had the alternative diagnosis been known at the time of allocation, should not be excluded from the primary analysis. These recommendations have a distinctly pragmatic flavor.

### 6.2 Adjustment for Noncompliance

In the preceding section it was argued that per protocol analyses should not be used to obtain explanatory estimates of the effects of intervention. The primary analysis should be by intention to treat.

The intention-to-treat approach presents little difficulty for pragmatic trialists. Pragmatic trialists understand estimates of the effects of interventions as estimates of the effect of the *intention* to provide the intervention, or of a *policy* to provide the intervention, rather than in terms of the effect of the intervention itself. More subtly, pragmatic trialists appreciate that the estimate is of the effect of the intervention when it is given in good faith to the people for whom it is thought to be appropriate, even though the intervention may sometimes, for one reason or another, actually be given to patients for whom it may be inappropriate. Similarly, effects are considered to be those measured at as close as possible to a target follow-up time, understanding that in practice the timing of this effect may be variable in practice. An intention-to-treat analysis provides estimates of effects of intervention that can be understood in these pragmatic terms.

Explanatory trialists may, however, be unsatisfied by estimates of effects of intervention based on simple intention-to-treat analyses. Explanatory trialists wish to know the effects of actually receiving an intervention, as distinct from the effects of intending to provide the intervention. This interest may stem from a desire to understand how the effects of intervention are mediated or, alternatively, from a concern about the generalizability of pragmatic estimates of effects of interventions [34, 35]. In recent years there has been a rapid development of methods that can be used to adjust intention-to-treat-based estimates of the effects of interventions to take account of protocol deviations. The focus has been on obtaining intention-to-treat-based estimates of the effects of intervention in compliant patients.

The simplest method for obtaining compliance-adjusted estimates of effects of intervention from all randomized participants applies to the situation in which participants either complied fully with the intervention or received, from the moment of allocation, the intervention they were not allocated. Newcombe has shown that, in this special case, the effect of intervention is attenuated by an amount that depends only on the frequency with which participants receive the intervention they were not allocated to [20]. The explanatory estimate of the treatment effect is the

conventional pragmatic estimate divided by an attenuation factor, which is simply the proportion of subjects in one group receiving the allocated intervention minus the proportion of subjects in the other group receiving the same intervention. The attenuation factor is always less than or equal to one, so the explanatory effect is always greater than or equal to the pragmatic effect. The validity of this estimate is contingent on the assumption that participants complied perfectly either with the allocated intervention or the alternative intervention from the time of randomization (i.e., it assumes participants did not "cross-over" some time after they had already experienced some of the effect of the allocated intervention or too late to experience some of the effect of the intervention they crossed over to). Insofar as participants cross-over after they have already experienced some of the effect of the allocated intervention, or too late to experience some of the effect of the intervention they crossed over to, this explanatory estimate will be biased upward.

Pocock and Abdallah describe a number of simple analyses they conducted to obtain explanatory estimates of the effects of intervention from a placebo-controlled trial of dexfenfluramine for obesity [36]. As they had data on the degree of compliance, they were able to regress outcome against compliance for participants in the experimental group. The regression equation was used to estimate the outcome of perfect compliers in the experimental group. An explanatory measure of the effect of the intervention could then be obtained by subtracting from this value the mean outcome for the control group. (A better approach, though one that was not possible with the data available in that trial, would be to subtract the estimated outcome of perfect compliers in the control group from the estimated outcome of perfect compliers in the experimental group.) A difficulty with this approach is that compliance may be both a determinant and an effect of outcome [37]. Comparison of outcomes of treated and control groups at the same level of compliance are potentially biased when the treatment and control conditions have different influences on compliance.

Sommer and Zeger circumvented this problem in their analysis of a trial of vitamin A supplementation on child mortality [22]. Compliance was treated as a dichotomous variable, so participants were considered to be either compliant or noncompliant. The approach was to infer virtual compliance levels in the control group by assuming that compliance levels in the control group were the same in the control and experimental groups. Unbiased estimates of the effects of intervention in compliant participants could be obtained by comparing mortality risk in the subgroup of compliant participants in the experimental group with the inferred mortality risk in the virtual subgroup of compliant participants in the control group.

Little and Rubin show that both Newcombe's approach and Sommer and Zeger's approach can be derived with causal models [38]. Causal modeling provides a rigorous framework for development of explanatory estimates of effects of intervention. The fundamental idea is that the explanatory effect of an intervention on any individual is the difference between the outcome that individual would have experienced with and without intervention. The obvious statistical problem is that, in a clinical trial, each individual either receives the intervention or does not. Nonetheless, given some often plausible assumptions, it is possible to estimate the average causal effect in compliant people. Causal models have been subject of active development in recent years. Bellamy and colleagues provide an introduction to the use

of causal models for obtaining explanatory estimates of effects of intervention in randomized trials [39].

There are two distinctly different ways of conceiving of explanatory effects of intervention. One possibility is to think of the explanatory effect of intervention in terms of the effect of intervention on the subpopulation of patients who comply (the conditional compliance-related treatment gain [35]). Alternatively, the explanatory effect of intervention could be thought of as the effect intervention would have had if all patients had complied with the intervention (the unconditional compliance-related treatment gain [35]). Estimation of these two quantities involves invoking different assumptions and involves different types of statistical models [39].

It goes without saying that any attempts to estimate the effects of intervention in compliant people can only be conducted if good data are available on compliance. Compliance is a complex construct that includes dimensions of consistency, intensity, and sustainability. Noncompliance may manifest as missed treatments, treatments in which the intervention was administered at an inappropriately high or low dose, or failure to continue with treatment. Unfortunately, it is often difficult to obtain good data on all these dimensions. Measurement of compliance is most often based on pill counts, patient diaries, and participants' self-reports [40], all of which may be biased. Usually, compliance data are reduced to a simple dichotomy, so that participants are classified as compliant or noncompliant.

## 7 REPORTING

The primary theme of this chapter has been that the design of a clinical trial should be strongly influenced by whether the intention is explanatory or pragmatic. Explanatory trials and pragmatic trials differ in the way they sample participants, administer the intervention and control interventions, measure outcomes, and analyze data. Authors of clinical trials should state explicitly, both in trial protocols and trial reports, whether their intention was explanatory or pragmatic. This will go some way to reducing misunderstandings that arise from the different intentions of trialists and readers of trial reports.

Pragmatic trialists are more interested than explanatory trialists in generalizing their findings to clinical contexts. (Perhaps a more accurate way to say this is that pragmatic trialists are more concerned that their findings can be used to make inferences about the care of individual patients.) The extent to which this is possible depends on the extent to which the characteristics of the trial participants and trial interventions resemble the participants and interventions about which inferences are to be made. Consequently, it is particularly important that reports of pragmatic trials provide detailed information about the characteristics of trial participants (patients and clinicians) and how the intervention was administered. Specific details should be provided about the strategies used to facilitate compliance with the intervention.

The conclusions of trial reports should be consistent with the design of the trial. Importantly, authors of explanatory trials should restrict their conclusions to claims about proof of concept. In the event that an explanatory trial provides evidence in support of the specific effects that were hypothesized, the conclusions should state just that. Explanatory trials should not make global claims about the effectiveness

of an intervention. Such claims should await demonstration of clinically important effects with pragmatic trials.

## 8 RECOMMENDATIONS

1. Clinical trials of interventions that are already in widespread practice should usually be pragmatic in orientation.
2. Run-in periods should not be used in pragmatic trials.
3. Pragmatic trials should sample participants (patients and clinicians) in as representative a way as is possible.
4. If sample size calculations for pragmatic trials are to be based on a hypothesis testing approach, they should incorporate empirical estimates of the smallest worthwhile effect of intervention, such as can be obtained with the benefit–harm trade-off method. Alternatively, sample size calculations for pragmatic trials could be based on considerations of the precision of estimates of effect, or of the value of sample information.
5. If the primary analysis of an explanatory trial is to involve adjustment of estimates for noncompliance, sample size should be adjusted accordingly.
6. Explanatory trials should blind participants and clinicians wherever possible. Pragmatic trialists should consider not blinding participants or clinicians.
7. In pragmatic trials the control group should receive the best available treatment alternative.
8. Pragmatic trials should have as endpoints either survival or measures that reflect quality of life or both.
9. The primary analysis of all trials, whether explanatory or pragmatic, should be conducted on an intention to treat basis.
10. Reports of clinical trials should explicitly indicate if the intention is to answer an explanatory or pragmatic question.
11. Pragmatic trials should provide detailed information about the characteristics of trial participants (patients and clinicians), how the intervention was administered, and the degree of compliance with the intervention.
12. Explanatory trials should not make global claims about the effectiveness of an intervention. Such claims should await demonstration of clinically important effects with pragmatic trials.

## 1 FOUNDATIONS FOR TRIAL DESIGN

The ethics of clinical drug trialing start with the concept of the trial that is to be undertaken. The trial must aim to answer a question that has not yet been answered, thereby necessitating the need for such a trial [1]. It should not be a substitute for a marketing strategy in which investigators place patients onto expensive agents for which either the patient or the formulary (namely the list of drugs available within a specific facility) cover the real costs of the trial, while the yield from the study contributes very little to scientific/clinical knowledge and more to treatment commitment [2].

The latter group of studies have a distinct advantage for the pharmaceutical company that is sponsoring them because they represent a pool of patients who would, otherwise,

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

possibly not receive the medication, were it not for the conduct of the clinical trial [3]. These studies generally lack scientific validity, and investigators need to think very carefully before committing to such questionable trials. Ethics committees also need to review the content of studies to make sure that they are not merely marketing tools masquerading as clinical trials.

The design of a study should include calculations to determine the sample size necessary to allow sufficient mathematical power to achieve a reliable response with adequate scientific rigor [4].

There needs to be consideration of the size of the response expected, the right dosage needed to attract such a response, the correct comparator (be it placebo, which theoretically equates to no comparator, or a proven therapeutic agent already known to be effective in the management of the condition under review), and the potential subject "dropout rate" that needs to be accommodated to achieve the desired final sample size upon which to base the study's analysis with adequate power [5].

It is often impossible to determine these parameters accurately as they may rely on earlier animal studies for extrapolation, and the animal data may not properly translate into human experience [6]. Alternatively, the concept may require an initial pilot study, in which far fewer subjects are involved but in which either the idea or the methodology under investigation can be tested. Such pilot studies may not truly reflect definitive data, but they will provide invaluable evidence to either support or refute the initial hypothesis [7, 8].

Pilot trials may be the only source of information upon which to base a foundation with which to ascertain indicative information to be used as the basis for calculations to determine a subsequent study that allows adequate power to truly answer the scientific question being posed. Often such pilot studies are difficult to publish as they lack the power to answer the question reliably, but their value should not be underestimated nor should the ethics of publication of such information be dismissed as they may represent the only proof of concept information [9].

The dosage of medication to be used in the trial may prove critical. Studies that have used too large a dosage cause unnecessary adverse events and hence delay or impede a drug's development or acceptance, as was the case with topiramate, which used a dosage of 200 mg in its trials [10, 11]. Conversely, the dosage that was used within the trial may be too low to achieve adequate response rate, thereby suggesting the agent to be less effective than it truly is, as was found with gabapentin [12]. Such errors have direct negative implications for the target patient population and may deny patient access to what amounts to an effective therapy because the study design was formulated on false expectations. It can be seen that innocent, but incorrect, assumptions may carry with them ethical consequences that may ultimately affect patient well-being because they affect the availability of appropriate therapeutic modalities [13].

The cost of conducting a trial has direct implications upon the adopted methodology. A crossover design is far less expensive than is a parallel arm design, and the purpose of the study must be decided. If the purpose of the study is to satisfy a regulatory requirement, then a parallel arms study design may be mandated by those regulatory authorities that are to determine the fate of the product under review [14].

The reason for reduced costs, in a crossover design, is that the subject acts as his or her own control, thereby allowing a significantly reduced sample size, as one patient serves in both arms of the trial to answer the study's question, which may effectively half the necessary sample size. This obviously reduces both the time delay and the effort it takes to recruit double the sample size and hence also reduces the need for additional investigators with inherent monitoring and infrastructure costs. Thus the purpose of the study may determine the study design, beyond any strict scientific or ethical requirements.

Where there is a need to have large numbers in a trial, then it often follows that the trial sponsors will resort to cost-cutting measures that may impact on the scientific rigor adopted for the protocol. An example of this is the use of large open-label studies to answer questions of comparative efficacy where the cost of a double-blinded methodology would be prohibitive due to the need for a "double-dummy approach" (in which both treatment A and treatment B need to have mirrored therapy with matched placebos such that the patient receives either treatment A, plus placebo, or placebo plus treatment B, thereby offering a potentially truly double-blind methodology) [15, 16]. The costs of such an approach might mean that the study would never have been feasible while the open-label design may still provide some very useful information.

The need to have large numbers recruited to a study may also translate into the inclusion of less skilled investigators, with far greater propensity for protocol violation and hence possible pollution of data. It is hoped that such potential problems do not translate into ethical expedience with insufficient external scrutiny of procedure.

It can be seen that the ethics of clinical research, and drug trialing, commence long before the first investigators are approached, the first study site is selected, or the first patient is recruited into the trial. The consideration of ethics starts with the selection of the scientific question to be asked, the capacity to answer that question, and the study design to be adopted for that purpose [17].

## 2 INVESTIGATOR SELECTION

For an investigator to accept to be part of a clinical trial requires that the investigator be confident that he or she can fulfill the requirements of the trial. This dictates that the investigator conducts a review of the purpose of the study, the question(s) to be asked in the trial, the methodology to be adopted, the types and numbers of patients sought for inclusion (reviewing inclusion and exclusion criteria), and the feasibility of conducting the study within the constraints of his or her center, while recognizing that all conduct within the trial must adhere to good clinical practice [18].

Many international trial sponsors will conduct a feasibility study of proposed investigators, but, as these are based on personal estimations, their validity is quite suspect [19]. Despite this shortcoming, the concept that each proposed investigator should at least assess his or her capacity to adequately conduct such a trial is very appropriate.

It is inappropriate, and ethically unjustified, to nominate oneself for inclusion as a prospective investigator within a trial if it is highly doubtful that one could accom-

modate the proposed trial's needs [20]. If selected as an investigator, the study sponsor automatically accumulates direct costs: such as investigator meetings, with its transportation and accommodation costs, costs for ethics committee submissions, and infrastructure costs [21].

There are basic considerations applicable to each nominated investigator. These include having adequate knowledge of the subject matter under consideration, having the resources to conduct the trial (be it space, staff, storage facilities, or standard operating and accounting procedures), having access to an acceptable and properly constituted ethics committee, and expecting to be able to recruit adequate numbers of appropriate patients to justify inclusion [22].

Without these ingredients, the proposed investigator should exclude him or herself.

The purpose of this discussion is to demonstrate that there are unequivocal ethical obligations on the investigator even before agreeing to be part of any investigative team. These obligations are often overlooked but to do so may cause unnecessary burden to a prospective sponsor. This may cause a sponsor to think twice about underwriting future studies, if investigators failed to meet their agreed commitments.

## 3 EXTERNAL STUDY APPROVAL

Once the aims of the study have been determined, the protocol established, and investigator sites selected, the study must then be subjected to external scrutiny.

All those who are involved with the conduct of the study (namely the company initiating the trial, the sponsor, the clinical research organization that will supervise the study, and the investigators) must review all the requirements [23], which may include contractual negotiations, privacy agreements, financial incentives, and infrastructure requirements, all of which should be available to the external review process as required by the relevant committees.

Submission to review boards, be they for scientific validity or for human research ethics committee (HREC) evaluation, are usually prepared in a predetermined fashion. The purpose of the HRECs is to protect the interests of trial subjects. Some, but not all, HRECs ask for a relevant expert scientific evaluation of a proposed protocol, before deliberating on the trial, so as to ensure that it is seeking valid scientific answers within the study design. This process should ensure that the study is not simply a marketing ploy. Such appraisal also seeks to confirm the feasibility of a study, its merits, and any potential risk that may, or may not, have been identified at the time of the submission. Some HRECs rely on their own members, which might include the relevant scientific expertise to provide the necessary scientific input. In either context, the role of the HREC is less to do with the scientific value of the proposed research (for which it can rely on others), and its main function is to focus its principal deliberations on the ethics of patient involvement [24].

The HREC reviews the protocols, the reasons for the study, patient safety, access to necessary information, format, content, and language of both patient information and consent documentation, access to investigators in case of any problems, and clear evidence of lack of coercion when recruiting patients [25].

This is of particular importance when the sample population is recruited from the clinical practice of an investigator, be it in the private or public practice of medicine. Patient protection is the fundamental obligation of the HREC [25], while at the same time it should not obstruct worthwhile research that may benefit the wider community.

Clinical trials can expose research candidates to new, and often unknown, risks when consenting to be subjects for a trial. To protect patients against such risks, the sponsors are expected to take out insurance to cover those risks should they eventuate [26]. More recently, members of HRECs have also sought insurance to indemnify their membership against potential litigation consequent to any adverse events that may occur within a trial. The HREC will often seek confirmation of appropriate insurance being in place before approving any study that involves human participation.

Studies that include live subjects (human or animal) cannot proceed without ethics committee approval, and, in the case of humans, a written consent or signed surrogate consent is needed from either the patient or someone responsible. Surrogate consent is "ideally a substituted judgment made by a person responsible for healthcare decision-making for a particular patient under the relevant legislation" [27]. The situations in which such surrogate consent may be required include evaluation of therapy for certain conditions, such as treatment in stroke patients for whom the capacity to decide is no longer valid. It may also be necessary to seek surrogate consent in underage subjects for whom guardian approval is mandatory. A similar situation exists for patients who lack the intellectual capacity to comprehend what is being asked of them within the trial protocol, as is the case with intellectually handicapped patients. For these patients it is also necessary to seek guardianship board approval, so as to relegate the authority to consent for such a patient to be included within any given trial, to a "responsible other" person who will have the patient's best interests as his or her primary concern [28].

## 4 CONSENT PROCESS

"Consent is widely believed to affirm the autonomous decision-making rights of prospective research participants, and their capacity to protect their own interests" [27]. Once the study has been approved by the external review process, each investigator assumes responsibility for the conduct of the trial within his or her institution, be it in private or public practice. This starts with a site initiation visit in which the sponsor, or surrogate, usually a clinic, also termed contract research organization (CRO), which is specifically contracted for the task, confirms that all those at the site are fully conversant with their obligations and the procedures to be adopted within the trial and that the center has the wherewithal to conduct the study [29].

With the emergence of CROs there has also emerged an understanding that they too have unequivocal ethical obligations. The level of sophistication impacting upon CROs have developed to the point of these being umbrella organizations designed to oversee compliance of its voluntary membership [30].

The investigator(s) then approaches suitable candidates regarding their willingness to participate within the trial. Each candidate must provide informed consent, based on provision of HREC approved study information, which clearly outlines

the purpose of study, the obligations imposed on both subjects and investigators, and the potential known risks and hazards that accrue consequent to participation in the trial. Each subject must have exercised free will, devoid of the imposition of undue influence, and must have the capacity to ask any questions that may have arisen, following the reading of the study information, before signing the informed consent document [22].

This process must be conducted in an open and unbiased fashion and the written consent should be witnessed and signed by a competent adult, recognizing that the written consent may be provided by a surrogate, representing the patient's best interests. Some may allow for the lack of equipoise in the doctor–patient relationship and have the trial coordinator initiate the consent process, following which the doctor will be available to answer any outstanding questions [26, 31].

It is imperative that the investigator must still be available to answer more difficult questions (which were beyond the capacity of the trial coordinator) and that investigator should countersign the consent form and confirm its authenticity [26, 31].

This goes some way to overcome any suggestion that patients, selected from the clinical practice of an investigator, have been coerced into participating in the trial. It is far easier to refuse participation within a trial if the request comes from a research coordinator rather than the doctor, especially if the HREC-approved study information includes a passage that guarantees ongoing clinical care by the doctor, irrespective of whether the prospective subject is willing, or not, to participate in the trial [26, 31].

The consent documents must acknowledge that trials of new therapeutic agents may not have encountered all possible risks and hazards that attach to the medication under experimentation. Potential subjects must be warned of the known risks and must also be advised that no one can guarantee that the trial will provide a direct benefit for them. Where a trial compares an investigative agent to a placebo, trial subjects must understand that they may not receive the medication under review, within the trial, and may receive the equivalent of a "sugar pill." They also need to be appraised of the risk ratio of this happening [29]. Similar advice needs to be given where differing doses of the study medication are to be given so that consent is truly informed. In short, the study protocol must be adequately described within the patient information and consent documents to clearly demonstrate that there has been no attempt to hide vital information or to give a false risk–benefit ratio [29]. The HREC has the responsibility to ensure that this has occurred and that the language used is of a sufficiently simple nature to avoid excessive use of jargon that may confuse a prospective subject. It must also be satisfied that the concepts, including the consent of information documents, are provided in a manner that is not too complicated for the average man/woman to understand [27].

Many trials of new medications adopt a blinded methodology, be it single or double blinded, and the potential subject must appreciate that he or she will not know what medication he or she will receive in a blinded study [15]. It is even more important for the subject to understand that, in the double-blinded methodology, neither the patient nor the doctor knows which medication the patient is taking during the trial. As mentioned earlier, the trial may use a placebo as the comparator. In such trials subjects will not know if they are receiving an active compound at all, in addition to the standard medications they were receiving before the trial. This

encapsulates the very essence of a randomized, placebo-controlled, double-blinded protocol. Most placebo-controlled studies do make provision for the patient to receive the experimental compound in an open-labeled, long-term safety and efficacy trial that follows the blinded study and that continues until the study medication is freely available. This must also be explained to potential trial subjects [23, 32].

Only subsequent to the free giving of informed consent, based on full disclosure, can the patient be included within the trial procedures [33]. Part of the consent process also includes provision for the withdrawal of consent, at any time throughout the study, without fear of compromising future ongoing clinical care by the doctor [33].

## 5 CONDUCT OF TRIAL

There is usually very little latitude to alter the conduct of a trial. All requirements and expectations of a trial are set out in the HREC-approved trial protocol, which stipulates the timing and conduct of the trial visit [22]. Unfortunately, all trials that include human subjects will also include errors made by either the investigating team or the subjects themselves. Some of these errors represent only minor infringements for which a waiver may be sought from the sponsor [29]. Other errors may be so significant as to dictate immediate exclusion and withdrawal from any further trial involvement. Should a waiver be approved, then the patient can continue in the trial and allowance is made for the deviation from trial protocol requirements.

If the patient experiences a serious adverse event (SAE), such as the occurrence of something that causes hospitalization or is life-threatening, then both the HREC and the sponsor need to be advised, as soon as is possible, following the investigator having been made aware of the SAE [34]. The necessary action that is to be taken, regarding the experimental agent, is at the discretion of the investigator, although everyone needs to be advised of the action taken. Depending on the nature of the SAE, and its cause, it may be necessary to advise all patients within a trial of the SAE, and it may also be necessary to amend the patient information and informed consent documents. The HREC, itself, may insist on this action and it may go so far as to terminate the trial if its members believe that continuation of the trial is no longer ethical or in the patients' best interests. Investigators must make the same considerations, and advise the HREC accordingly, thereby demonstrating that the investigator also holds the well-being of the trial subjects as his or her primary concern for continuation of any given trial [34].

Others who are trialing the same medication—either for a similar indication or an alternatively indication—and who encounter an SAE—must also notify their appropriate authorities, such as their HREC, sponsor, or CRO. They, meaning the sponsor or CRO, must notify all other investigators who are/were trialing the same agent. Once notified of these SAEs encountered by others, it is imperative that the investigator also bring these to the attention of their HREC in the same fashion as they would have done had they personally encountered the SAE [29]. This further ensures maintenance of informed consent, should any of the SAEs have a bearing on the decision to continue a trial, be it from the perspective of the investigating team or subject.

Based on the SAE reporting, the HREC may seek clarification to determine if: the trial should continue with its currently recruited subjects; if continuation of recruitment should be allowed, if the entire process should be aborted, or if there needs to be an amendment to the current informed consent and information documents; and if the informed consent process needs to be repeated with each subject who is already within the trial to expedite their withdrawal should they choose not to face further previously unforeseen risk [29].

Depending on the nature of an adverse event, there may be need to unblind the blinded randomized data to determine whether the patient was exposed to the experimental compound and, if so exposed, the dosage of the exposure. Again this is at the discretion of the investigator, but it remains imperative that the patient's well-being must assume primal consideration [34]. This takes priority over any secondary ethical obligation that the investigator may have to the sponsor of the study to adhere to trial protocol as it relates to blinding of treatment arms.

Upon completion of the trial, the subject may either elect to continue on the study agent, if an open-label study is to follow, or choose to stop whatever it was that they were taking during the trial [23]. It must be remembered that trial subjects may not be advised of what they were taking during a double-blinded study, even after they complete that part of the trial, if not all subjects have completed the study. This is considered important to maintain mathematical integrity when analyzing the study data, but it does raise important ethical considerations as the decision to continue within the open-label arm is often based on inadequate information, in the absence of knowing what was taken during the trial. Some patients may think that they had a real benefit from the study medication when in fact they were on placebo, while others who were on the study medication may have thought they were on placebo [35]. Thus far there has not been an adequate resolution to this mathematical and ethical dilemma, which still needs to be resolved on a consensus basis.

The question of conducting an open-label study, following completion of a blinded protocol, is also of ethical importance [32]. Access to the study medication, following involvement in a blinded study, is often considered as an inherent ethical consideration, even at the time of the initial HREC approval for the blinded study to be undertaken. It is considered important to ensure that patients, who consider that they have benefited from the study medication, be allowed to continue on it until the medication is available on the market at a reasonable price, especially where a formulary exists, as is the case with the government-sponsored Pharmaceutical Benefits Scheme (PBS) in Australia [23, 36, 37].

## 6 AFTER STUDY COMPLETION

Responsibility for the trial consequences does not automatically stop once the last subject has completed his or her trial commitments. Insurance against the delayed expression of adverse effects is expected to be maintained long after the study has been completed and at least for one year. Ongoing support of patients, access to effective treatment, and notification of subsequent SAEs remains obligatory to ensure that patient safety is maintained [29, 34].

What is often less clear-cut is the ethical requirement to publish the findings of the study once the results become available. Current opinion supports an ethical

obligation to make the findings of any study publicly accessible, to ensure the widest dissemination of all results, be they positive or negative [38]. To satisfy this obligation, it is mandatory for journals to provide equal space for both negative and positive studies, something that is often claimed but not necessarily satisfied or realized with the current perception being that positive studies are far easier to publish than our negative studies [39, 40].

## 7 CONCLUSION

The ethics of clinical drug trials start at the time of establishing what question(s) should be asked, and answered, as a consequence of the trial. The response to these issues influences every step along the way, up to and including posttrial follow-up.

Issues that have not been canvassed within this treatise include those ethical obligations that represent the responsibility of trial subjects to adhere to their commitments to follow trial dictates. It behoves all those concerned with the conduct of the trial to recognize that trials represent a very expensive and demanding exercise that must adhere to the requirements as stipulated within the relevant protocol. Other issues, not addressed in the above analysis, include the ethical obligations that should be addressed by the company that sponsors the trial. These obligations should include the maintenance of rigorous postmarketing surveillance concerning the product being trialed, to protect against unexpected SAEs, as occurred with such medications as vigabatrin, which caused specific visual field defects that were only recognized years after the drug had come to market [41]. It may also be relevant to conduct postmarketing studies that better reflect the true use of products to see if clinical practice truly reflects what was demonstrated as a consequence of regulatory determined trials [42–44].

## 1 INTRODUCTION

> "It is not enough that you should understand about applied science in order that your work may increase man's blessings. Concern for man himself and his fate must always form the chief interest of all technical endeavors."
>
> —*Albert Einstein, Address to the California Institute of Technology, 1931*

> "There is the more reliable safeguard provided by the presence of an intelligent, informed, conscientious, compassionate, responsible investigator."
>
> —*Harry Beecher, New England Journal of Medicine, 1966*

The quest for new treatments to alleviate suffering and prevent disease is indeed a very noble cause. Medical research has the potential to create huge benefits to society and enhance the professional reputation of the researchers who are responsible for these discoveries. However, a researcher must never forget that concern for the participants of human research is paramount, irrespective of how important the research outcomes are to society in general. A researcher must never knowingly seriously compromise the welfare of a research participant—"the ends must never justify the means." According to Harry Beecher, careful training of researchers in both biomedical and ethical concerns is the key to preventing or minimizing serious mishaps. Therefore, the aim of this chapter is to educate clinical researchers in the common pitfalls of human experimentation and ways to avoid these ethical problems in pharmaceutical trials.

## 2 ETHICAL DILEMMAS CENTRAL TO CONDUCT OF CLINICAL RESEARCH

Ethics is a branch of philosophy that is concerned with answering the age-old questions about duty, honor, integrity, and justice. Research ethics is a branch of applied ethics that studies the ethical problems, dilemmas, and issues that arise in the conduct of research. Within the field of clinical trials three key ethical dilemmas often arise [1]:

1. *Good of Individual Versus Good of Society* Central to all moral theories is the need to respect and promote the rights of an individual. Natural or universal rights are those rights which are inherent in the nature of people and are not contingent on human actions or beliefs nor do they require legal enforcement by government or society. Philosophers believe that the rights to life and liberty (ability to act according to his or her own will) are the two guiding principles of natural rights. On the other hand, the promotion of social welfare of the community in general is also a central tenet in moral philosophy. Unfortunately these moral principles of respect for an individual's natural rights and the needs of society are often in conflict in the setting of clinical research. It is vitally important to use human subjects in research in order to gain valuable scientific knowledge that can benefit all of society, but this research has the potential to place individuals in harm's way and compromise their natural rights. Therefore the central ethical question in all clinical research is how best to protect the universal natural rights of an individual without compromising the scientific validity and social value of the research.

2. *Net Result of Risks Versus Benefits* In any clinical research setting with the potential to harm the participant physically or mentally, the researcher has an ethical obligation to ask the question whether the benefits of the research to the participant and/or the community in general outweigh the risks to the individual. It is normal to assess risks/benefits in terms of probability and magnitude and in the context of the underlying health status of the trial participants. For example, it would be considered unethical to conduct a research study for a medication with even a low risk of death (1%) in the setting of a non-life-threatening medical condition such as dermatitis or alopecia. However, it may be ethically acceptable to enroll terminally ill patients with grade IV astrocytoma in a trial of a new chemotherapy medication with a 1% chance of medication-induced death if this trial treatment gives them any real chance of cure. Conversely, it may be acceptable to place healthy phase I trial volunteers at significant risk of mild reversible adverse events such as headaches or nausea, but it is totally unacceptable to place them at any material risk of death or irreversible disability.

3. *Just Distribution of Benefits and Harms* All human experimentation raises the important ethical dilemma of equitable distribution of benefits and harms. The potential benefits to an individual of being involved in medical research include access to new potentially more efficacious treatments, supervision of clinical care by highly qualified medical staff with intensive monitoring, identification of secondary pathology during the trial entry examination, financial support, and improved self-esteem. Many people gain considerable benefit from knowing that their participation in research is advancing medical science, thereby helping other people in the future with the same medical condition that they are experiencing. Such altruistic motivation is a common positive psychological benefit of trial participation. Conversely, involvement in a clinical trial may create harm. The trial medication may produce physical or psychological adverse effects ranging from the relatively benign through to death. For example, if the participant is allocated to the placebo arm of a study, their involvement in research may delay or block their access to already established effective treatments. Finally, many trial designs require extensive monitoring which can be intrusive and tiresome to an individual whose quality of life may already be diminished by their underlying disease. If the benefits

of participation in a trial are likely to exceed the potential risks, natural justice would dictate that any individual, regardless of their age, race, gender, religion, or financial resources, should have equal access to the trial.

## 3 PHILOSOPHICAL THEORY AND CLINICAL TRIAL ETHICS

Philosophers have developed several different ethical theories/principles which may assist in making the morally correct decision in the field of clinical research [2]. The following discussion will summarize the main components of the three most useful theories/principles in the field of research ethics. Each of these theories/principles has its own strengths and weaknesses, making it important to not analyze a clinical research dilemma from a single philosophical point of view.

### 3.1 Deontological Theory (Kantianism)

Deontological theory is an approach to ethics that focuses on the rightness or wrongness of actions themselves, as opposed to the rightness or wrongness of the consequences of those actions [2]. It can be summarized succinctly as an ethical theory based on "moral duty or obligation." The German philosopher Immanuel Kant (1724–1804) is generally considered as the father of deontological theory. Kant claimed that an action is morally wrong, irrespective of the final outcome, if it is inconsistent with the status of a person as a free and rational being [3]. The duty to promote an individual's freedom and rationality is the guiding ethical principle of Kantianism, referred to as the categorical imperative. Stated differently, Kantianism requires an individual to treat both themselves and others as ends in themselves, never only as means to an end. All human beings have intrinsic moral dignity and we should not abuse, manipulate, harm, exploit, or deceive people in order to achieve specific goals, no matter how desirable that goal may be. Put quite simply, deontological theory can be condensed into "the ends never justify the means" and "do unto others as you would have done to yourself."

### 3.2 Utilitarianism

The basic guiding principle of utilitarianism is that the morally right thing to do is to produce the best overall outcome for the most number of people. The English philosophers Jeremy Bentham (1748–1832) and John Mill (1806–1873) developed the theory of utilitarianism [4]. Mills stated that the morally correct action was the one which created the greatest balance of happiness for the greatest number of people—somewhat akin to a moral "cost–benefit" analysis. Where deontological theory prohibits placing clinical trial participants at significant personal risk for the benefit of science or the community in general, utilitarianism states that this is ethically sound provided the expected outcomes for society are favorable. Utilitarianism is a commonly used theory in medical research as investigators and institutional review boards (IRBs) are always trying to find the appropriate balance between personal risk and benefit for the trial participant versus the benefits to society in general.

### 3.3 Principlism

The term *principlism* is used to describe four standard principles outlined in the Declaration of Helsinki [5] and the Nuremberg Code [6] that govern ethically responsible research practice. These principles include respect for autonomy, nonmaleficence, beneficence, and justice [7]. Principlism is not derived from a single philosophical theory, but rather combines several different philosophical perspectives [1]. For example, the right of individual freedom or autonomy is central to deontological theory while beneficence or the generation of "greater good" is a key feature of utilitarianism. As principlism borrows the best features of the available philosophical theories, it is generally considered the most applicable to resolving ethical dilemmas in medical research:

(a) *Autonomy* Autonomy is the basic human right to respect an individual's ability to make their own decisions regarding their own health and future. If a researcher is to respect an individual's right for self-determination, he or she must create a situation where the research subject is able to make an autonomous decision regarding participation in the research. This can only be enabled by providing adequate information about the participant's involvement in the trial (informed consent) and avoiding undue influence or coercion. To achieve informed consent, subjects must be given adequate information regarding the research procedures that they will undergo, the risks and benefits of being involved, and alternative medical therapies of proven benefit outside the clinical trial. This information must be provided in both oral and written form in simple lay language that can be easily understood by a person with only basic language skills. Furthermore, all study participants must enter voluntarily, free from coercision or undue influence, and understand that they may withdraw at any time. The provision of excessive financial reward or the threat of withdrawal of standard medical care would be considered an unethical violation of the ethical principle of subject autonomy.

(b) *Beneficence* Beneficence refers to actions likely to promote individual well-being and/or benefit others.

(c) *Nonmaleficence* The concept of nonmaleficence is best embodied by the Latin phrase *primum non nocere* ("first do no harm"). To avoid doing harm has been a guiding principle of medical treatment since the advent of the Hippocratic oath. Medical researchers have both a moral and legal obligation to avoid "unjustified" harm to trial participants. Some harm may be justifiable provided that the benefits outweigh the negatives. All medical research must be assessed on the balanced probability of harm versus benefit according to the ethical principles of beneficence and nonmaleficence.

(d) *Justice* Justice requires that there be fair procedures and outcomes in the selection of research subjects. The burdens and benefits of research must be equally distributed to include individuals of both genders, different ages, and various racial and ethnic backgrounds, not just the easily available or vulnerable to facilitate trial recruitment. In the past researchers have targeted middle-aged white men for trials, avoiding recruitment of children and women of reproductive age. This produces an injustice as it creates an inequality in medical understanding of how a particular treatment may work (or not work) in children and women while robbing these

disadvantaged groups of the opportunity to benefit from new clinical trial treatments.

## 4 HISTORICAL TRIGGERS FOR DEVELOPMENT OF CODES OF ETHICAL RESEARCH PRACTICE

Clinical research using the established scientific method of hypothesis generation, observation, and experimentation has been conducted throughout the world for many centuries. However, only relatively recently have such medical experiments been placed under the scrutiny of ethical analysis and the nature of human experimentation limited by published ethical guidelines. Unfortunately many researchers have either been ignorant or intentionally subjugated these established ethical principles, often leading to disastrous consequences. Some of the best known and studied examples of human experimentation gone awry are outlined in the paragraphs below as examples of why clinical research requires enforceable ethical guidelines to protect research participants and society alike.

The Tuskegee experiment is an example of medical research that breaks almost every ethical principle [1]. In 1929 the U.S. Public Health Service commenced a study to examine the prevalence of syphilis among poor uneducated blacks and its possible mechanisms of treatment. The study confirmed that mass treatment of syphilis was feasible and desirable, but by 1932 funding for treatment was suspended due to lack of money created by the Great Depression. However, in the town with the highest prevalence of syphilis (Tuskegee, Alabama) it was decided that researchers would continue to monitor participants for the long-term complications of untreated syphilis, thereby ascertaining the natural history of the disease in African Americans [8, 9]. Participants were administered "therapy" which was known to be ineffective (mercurial ointment and spinal taps) and coerced into being involved in the research by being offered financial incentives such as provision of free medical "care" and payment of funeral expenses! The Tuskegee research participants were not told that they had syphilis but rather "bad blood" and they were not offered alternative medical treatment, despite penicillin becoming an established medical cure for syphilis as early as 1945. It was not until 1972, following considerable public outcry, that the U.S. Department of Heath, Education and Welfare (DHHS) closed the study. This unfortunate experiment breaks several established ethical principles, including the right of participants to make an informed unbiased choice regarding their involvement in research (autonomy), the need to maximize individuals' well-being while minimizing harm (beneficence, nonmaleficence), and justice [9].

Medical experiments conducted by Nazi doctors of the Dachau, Auschwitz, and Buchenwald concentration camps are one of the worst examples in history of a researchers' subjugation of their ethical duties to research participants. These doctors were proponents of racial hygiene theory, which stated that people of non-Aryan background such as Jews were subhuman and therefore should not be afforded the same basic human rights as the Aryan people. As such, the Nazis believed that they were free to conduct experiments on concentration camp prisoners that can only be described as barbaric. These experiments included subjecting prisoners to extremes of temperature and pressure, ingestion of seawater, limb transplants

without medical need, injection of infectious agents to determine the effectiveness of new antibacterial drugs or vaccines, deliberate inflicting of skin wounds to provide an experimental model to assess new forms of wound therapy and exposure of subjects to high doses of radiation [1, 10]. In all of the experiments the aim was to gain knowledge that was helpful to the German military, not the treatment of underlying prisoner ailments. Furthermore, prisoners were not told what would happen to them, were not given the opportunity to refuse consent, and were not offered established medical treatment when complications arose. These gross violations of basic human rights and ethical principles by the Nazis during World War II were the impetus for the development of the first formal international guideline on the ethical conduct of medical research, the Nuremberg Code (1949).

There are many examples of researchers using vulnerable subjects for research to help facilitate recruitment [1]. In the 1950s New York University conducted experiments in which mentally retarded institutionalized children from Willowbrook State School were deliberately infected with hepatitis virus to enable study of the natural progression of the disease. These children's parents had unfair inducement applied by researchers to give their consent by offering to expedite admission of their children to the school if they agreed to be involved. Between 1960 and 1972 the Defense Atomic Support Agency funded a research program in which low-income, poorly educated principally black patients with cancer were administered massive doses of whole-body irradiation as a "treatment." Despite there being no scientific justification for treating a localized cancer with whole-body irradiation, this study was conducted so that the military could assess human tolerance to radiation exposure and effective methods of treatment. Finally there are multiple examples of prisoners being subjected to dangerous exposures of infectious agents and radiation in the interests of medical research. While many of these prisoners were informed of the nature of the experiments, they were coerced into involvement by incentives such as early release from prison or gifts of money and cigarettes. In the prison system, where an individual's liberties are severely limited, such coercion does not allow unbiased informed consent.

## 5 DEVELOPMENT OF GUIDELINES FOR ETHICAL CONDUCT OF MEDICAL RESEARCH

### 5.1 Hippocratic Oath (Fourth Century BC)

The Hippocratic oath is an oath taken by physicians governing the ethical practice of medicine. It is believed that the oath was written by Hippocrates, the father of medicine, in the fourth century BC. While the contents of the oath do not pertain directly to medical research, they do set down some valid ethical practices to which physicians conducting clinical trials should aspire. Two components of the oath have special relevance to the ethical practice of clinical research. First, Hippocrates outlines the need for nonmaleficence and beneficence in the phrase "I will prescribe regimes for the good of my patients according to my ability and my judgment and never do harm to anyone" and the decree to keep "myself far from all intentional ill-doing." Second, he speaks of the importance of educating the next generation of physicians. In the broadest sense, one can draw parallels between this requirement

for education and the ethical requirement for researchers to share knowledge gained during research with the general community.

### 5.2 Nuremberg (1949)

Following the end of World War II trials of war criminals were conducted before the Nuremberg Military Tribunal in order to investigate and punish those individuals who committed crimes against humanity. Specifically, they were in response to the inhumane Nazi human experimentation carried out during the war by individuals such as Dr. Josef Mengele [2, 10]. During the trial several of the accused argued that their experiments differed little from prewar experiments and that there was no law that set the boundaries differentiating legal from illegal human experimentation. Dr. Leo Alexander then submitted to the tribunal a list of six points that defined what should be considered legitimate human medical research. These six points were adopted by the trial verdict and an additional four points were added—together making the 10-point Nuremberg Code governing ethical human experimentation [6]. The contents of the Nuremberg Code are outlined in Appendix A. In summary, the code outlines the need for ensuring participant autonomy (Articles 1 and 9), beneficence (Article 2), and nonmaleficence (Articles 3–8 and 10) during human experimentation.

While an excellent starting point in the development of guidelines to govern ethical human experimentation, the Nuremberg Code was lacking in several key areas. First, the code contained no guidelines concerning the ethical conduct of research on individuals who are unable to given informed consent (e.g., children, mentally impaired, and critically ill). Second, it totally ignored the need for maintaining participant confidentiality and the need for justice regarding individual's opportunity to engage in medical research. These deficiencies were later addressed in the Declaration of Helsinki [5].

### 5.3 Declaration of Helsinki (1964)

The Declaration of Helsinki [5] was developed by the World Medical Association (WMA) as a set of ethical principles for physicians and other participants in medical research. It was originally adopted in 1964 in Helsinki, Finland, and has since undergone eight revisions, the latest significant revision occurring in 2000 (Appendix B). The declaration covers all of the major ethical protections outlined in the Nuremberg Code but also contains several important additions:

1. *Article 1* The declaration states that human material and identifiable human data require the same ethical protections given to individuals undergoing direct human experimentation. This means that researchers are not able to conduct experiments using human tissue/blood samples collected for a nonrelated purpose without the consent of the original research participant. Similarly, researchers are not able to use databases containing confidential medical details of individuals for the purposes of research without first gaining these individuals' informed consent.
2. *Articles 8 and 23–25* Here the declaration discusses restraints required for the ethical conduct of research on "vulnerable persons" such as children, the

mentally incompetent, and subjects in a dependent therapeutic doctor–patient relationship with the researcher.

3. *Article 9* The declaration states that the ethical protections set forward by the declaration cannot be reduced or eliminated by local legal or regulatory requirements but these protections should be considered universal worldwide.
4. *Article 12* Here the declaration states that due care for the environment and welfare of animals must be taken into consideration during the conduct of medical research.
5. *Article 13* There is an absolute requirement that all human research protocols should first be reviewed by an independent committee of relevant experts (ethical review committee) to ensure that the study design is scientifically robust and provides adequate protection of research participants.
6. *Article 21* This stresses the need for maintaining participant privacy and confidentiality.
7. *Article 27* Both authors and publishers of scientific journals have an obligation to honestly disclose the results of both positive and negative outcomes of human experimentation. Furthermore, any potential source of conflict of interest must be declared in all publications.
8. *Articles 29 and 30 and Associated Clarifications* Following public outcry concerning the use of a placebo in a U.S. Center for Disease Control study of the antiviral zidovudene to prevent perinatal transmission of HIV in the developing world, the declaration's provisions on acceptable "alternative care" were revised (2000). This revision held that developed-world standards of care should apply to the conduct of clinical trials in the developing world, irrespective of whether this standard of care is actually available to the public through the existing heath system. While the current declaration does not expressly prohibit placebo-controlled studies, it does set out some significant limitations. Article 29 states that "the benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic, or therapeutic method exists." The declaration then goes on to state that it is acceptable to use a placebo in a research study where there is a proven alternative therapy provided that the condition being studied is a relatively minor one and the research participant will not suffer any irreversible harm and all research participants allocated to the placebo arm will later be offered the best available proven therapy at the conclusion of the study.

### 5.4 National Research Act (1974) and Belmont Report (1979)

Although the Nuremberg Code and Declaration of Helsinki provided excellent guidelines on what constituted the ethical practice of medical research, they did not have the power of legal mandated enforcement within individual countries. Starting in the United States, the Surgeon General (1966) and later the U.S. Food and Drug Administration (FDA) (1971) mandated prior peer review of all

human research protocols funded by the National Institutes of Heath or regulated by the FDA. This in turn led to the development of the National Research Act (1974), which mandated that any government-funded medical research would first require review and a pass judgment on the acceptability of the proposed research by an independent IRB. Furthermore, the regulations set down rules which would govern the composition of these IRBs, such as a mixture of men and women, scientific and nonscientific members, as well as general community members. The composition of these boards was to ensure that they had the capacity to assess the scientific validity of the research proposal as well as that ethical principles such as distributive justice, participant safety, and autonomy were respected while blocking research with the potential for inciting moral outrage in the general community.

When the National Research Act was signed into law on the July 12, 1974, The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was formed. This commission was charged with developing guidelines that should be followed during all human medical experimentation. The results of nearly 4 years of deliberations by the commission were published in 1979 as the landmark Belmont Report [11]. As would be expected, the report focuses on the need to respect participant autonomy, the need to maximize good (beneficence), and the application of justice.

### 5.5 CIOMS (1982)

The Council for International Organizations and Medical Sciences (CIOMS) was formed in 1949 by the World Health Organization (WHO) and the United Nations Scientific and Cultural Organization (UNESCO) with the goal to facilitate and promote international activities in the field of the biomedical sciences. As part of this mandate, CIOMS undertook important work in the field of bioethics during the 1970s, culminating in the publication of the "International Ethical Guidelines for Biomedical Research Involving Human Subjects" in 1982. This work has since been updated in 1993 and 2002 and is available in print [12] or online via the CIOMS website (http://www.cioms.ch/; CIOMS 2002 guidelines). The CIOMS document consists of 21 guidelines governing the ethical conduct of human biomedical research. These guidelines are heavily based on those contained within the Declaration of Helsinki but also contain several important practical discussions on how best to implement ethical principles in the design and conduct of a research. For example, guideline 4 stresses that informed consent is a continuing process that should be conducted throughout the life of a study, not just an event at the commencement of a participant's enrollment in a research study. The CIOMS document provides a very useful 26-point checklist that helps ensure that all the requirements of proper informed consent are met by a study [12]. Guideline 7 outlines in very practical terms what level of financial reimbursement is ethically acceptable for involvement in a trial and what would be considered unacceptable financial inducement. Appendix 1 of the CIOMS guidelines outlines the 48 individual points of discussion that need to be addressed by all research submission to a Human Research Ethics Committee/IRB to enable proper determination of the ethical merits of the proposed research.

### 5.6 National Guidelines on Ethical Conduct of Human Research

Most countries have their own guidelines governing what is ethically acceptable practice in the field of human experimentation. The Office of Human Research Protections, DHHS, publishes a summary of the individual regulations and legislation covering human research in 79 individual countries and two confederations (European Union and the Commonwealth of Independent States). This summary is updated regularly and can be located on the Office for Human Research Protections website [13]. While the legislation enacted in each country may differ, it should be stressed that no national ethical, legal, or regulatory requirement should be allowed to reduce or eliminate any of the protections for human subjects set forth in the Declaration of Helsinki (Article 9, 2000).

## 6 ETHICAL ISSUES IN DESIGN, CONDUCT, AND REPORTING OF MEDICAL RESEARCH

The aim of this section is to make the reader aware of aspects of the ethical debate surrounding the design, conduct, and reporting of a clinical trial. Several issues which are discussed in previous chapters are not discussed in detail here. These include stopping a clinical trial (Chapter Monitoring), the role of Data and Safety Monitoring Committees (DSMCs) and ethics committees (Chapter Clinical Trials Data Management), and patient records and privacy (Chapter Review Boards). It is further recognized that as the ethical debate is evolving, guidance documents and ethical codes are revised at regular intervals, and new legislative changes are under consideration. For example, at the time of this writing, the Declaration of Helsinki is being revised [5], an update of the CONSORT statement is being prepared [14], and federal legislation requiring disclosure of clinical trial results is being considered in the United States [15]. Therefore, where possible, we have provided current website addresses that direct the reader to the latest versions of the relevant documents (Table 1).

It is further noted that the ethical conduct of clinical trials extends beyond the study design, conduct, and reporting. Appropriate attention to the quality of manufacture of investigational drugs, validation of methods, and demonstration of stability underpins ethical evaluation of new drug candidates. Such considerations are now mandatory in most regulatory territories. In addition, when conducting nonclinical safety studies to support clinical trial programs, researchers must be aware of the applicable quality systems—Organisation for Economic Co-operation and Development (OECD) principles for good labor practices (GLP) [16]; GLP regulations, Code of Federal Regulations (CFR), Title 21, Part 58] [17]—and the Declaration of Helsinki, Article 12, which states that "the welfare of animals used for research must be respected" [5].

### 6.1 Gold Standard: Randomized Clinical Trial

A necessary, although not sufficient, condition for any experiment on human subjects is that the study is scientifically sound [18]. The principle of beneficence includes the requirement that the hypothesis being tested has scientific merit, that the design of the study adequately addresses the hypothesis, and the outcomes

of the study are valid. Beneficence further requires that investigators are competent to conduct the study and they seek to minimize the risks and maximize the benefits of the research [12]. The "gold standard" for determining the efficacy and safety of a new therapeutic intervention is the randomized controlled trial (RCT).

*Randomization* aims to eliminate systematic differences between treatment groups [19]. It removes any selection bias that may be introduced by those conducting the study and, ideally, balances confounding variables (some of which may be unknown) among the treatment groups, thus preventing "covariate imbalance" [20]. By diminishing the chance that baseline confounding variables differ among the treatment groups, the validity of conclusions relating the study outcomes to the intervention under investigation is enhanced. A more detailed discussion on randomization procedures is provided in Chapters Methods of Randomization and Randomized Controlled Trials.

*Blinding* involves the effective masking of both the investigational drug and control treatments (e.g., a placebo or comparator drug) in an attempt to ensure that all those involved in the study (i.e., trial participants and trial staff) do not alter their behavior in response to the knowledge of which treatment is being administered. In a "double-blind" trial, treatment allocation is unknown to the participant, investigator, sponsor, and trial staff, including those assessing outcome measures. Blinding thus aims to minimize potential bias in the management, treatment, and assessment of trial subjects that may otherwise occur if the treatments were known [19]. The term "single blind" refers to studies where one party (usually the subject) is blinded to treatment allocation.

The design of the RCT raises many complex ethical issues. For example, how can investigators be asked to suspend the principles of individualized patient care inherent in the Hippocratic oath and, blinded to prospective treatments, allow their patients to be randomized receive an experimental or control therapy? Further, can the use of placebo as a control be justified if currently available therapies are known to effectively treat the condition under investigation? How can a clinician condone trial-based medical procedures (e.g., the taking of biopsies) that have no therapeutic benefit for the patient? Indeed, should the roles of treating physician and clinical investigator be separated and filled by different individuals?

From the trial participant's perspective, does an RCT—in requiring patients to delay knowledge of their treatment until the randomization code is broken—contravene the principle of autonomy that would allow individual patients to determine which treatment they receive?

Ethical frameworks for the conduct of a clinical trial, with reference to ethical codes, are briefly introduced in the following sections.

## 6.2 Ethical Frameworks for Conduct of Clinical Trials

The concept of uncertainty in outcome, or "equipoise," has been invoked by many authors to resolve ethical considerations inherent in the conduct of an RCT. According to this paradigm, equipoise exists if the outcome of a trial is sufficiently uncertain such that an individual participating in the trial will not be disadvantaged; under these circumstances, enrollment in the trial is therefore considered "an equal bet in prospect" [21] and participants should not be harmed by random

allocation to a given treatment arm [22]. A trial in equipoise should, therefore, be acceptable to both Kantian and utilitarian philosophies [21], both of which seek to balance the duties and rights of the individual and society (see a brief description of each above). Thus, in the presence of true equipoise, individuals can, in theory, contribute to the wider medical knowledge at no cost to themselves [23]. The application of the concept of equipoise does, however, raise several questions. For example:

1. *From whose point of view should equipoise exist?* Options include the individual investigators, the clinical research community ("clinical equipoise," after Freedman [24]), or the prospective patient. Many commentators would consider equipoise as essentially a characteristic of the informed, competent patient [21]. Importantly, a trial that may be considered to be in equipoise for one trial participant may not be for another [23].
2. *What degree of equipoise should exist?* Any given outcome in a clinical study is rarely an "even bet." As a therapeutic candidate moves through the development process, a significant body of knowledge accrues, and it is unlikely sponsors would continue development unless previous nonclinical and clinical studies were favorable. Moreover, most published industry-funded trials report a positive outcome in favor of the drug candidate under investigation [22, 25]. This finding is not explained by publication bias alone and suggests that, in reality, very few industry-sponsored trials are in true equipoise. The question then becomes: At what point of "equipoise imbalance" does a trial become unethical? One study found that 50% of subjects perceived a trial to be unethical when 70% of experts favored one arm of the study; if this figure rose to 80% of experts, less than 3% of subjects thought a trial is justifiable [26].
3. *At what point is a decision regarding equipoise made?* The key decision faced by most trial participants is whether or not to consent to randomization. Equipoise in this context would mean the prospective participant perceives that agreeing to randomization gives them an equal chance of a good outcome as not participating in the trial [27].

The concept of equipoise has many critics. Some consider that the term lacks consistency, reality, and utility [28], while others maintain that it disregards the autonomy of the subject [22] and is fundamentally incoherent [29, 30]. Alternative ethical frameworks for the conduct of clinical trials have been proposed, including the "positive expected outcomes" [22]. Under this model, the trial participant would base a decision to participate in a given study on the pooled average of expected outcomes in all arms of the trial before randomization. In this context, some authors have noted that many trial participants achieve above average clinical outcomes even though the trial may have reported a negative result or the patient received a control treatment [31, 32]. Several reasons for this observation have been cited, including the cyclical nature of the disease being studied [20], the contention that clinicians who recruit to trials tend to be better clinicians [31], and the possibility that the strict protocol-driven procedures (often overseen by expert committees) provide a superior standard of care. It is emphasized, however, that improved medical care should not be offered as an inducement to participate in a clinical trial.

### 6.3 Ethical Issues in Clinical Trial Design: Study Power and Control Groups

***Study Power*** The social value and scientific validity of a study are critical to the ethical conduct of clinical research. Exposure of trial participants to even minor risks cannot be justified if the study is poorly conducted or is of little scientific merit. It if often argued in this context that underpowered trials that yield outcomes that are not clear-cut have the potential to mislead and are therefore unethical. In contrast, others would maintain that, if equipoise truly exits, then there is no ethical objection per se to participating in an underpowered study [21]; the patient does not "lose out in prospect." While this contention would seem to contravene a central tenet of ethical clinical research that demands validity and scientific rigor, there are examples where an underpowered trial may be better than no trial at all or where an underpowered trial represents a key step in the drug development process. These include studies on rare conditions, where alternative sources of data may be used to support the trial results, and early-phase studies that aim to determine estimates of efficacy and safety [33]. The authors point out that, in both cases, prospective participants should be informed of how the trial data may be used (e.g., inclusion in a subsequent meta-analysis) and that the trial may only indirectly contribute to health care benefits.

***Placebo-Controlled Trials*** Significant ethical concern and debate surround the use of placebo treatments as a control in a clinical study. Some authors have invoked the concept of equipoise to argue that, if an effective treatment is available, then placebo-controlled trials are unethical because equipoise cannot exist [21]. In contrast, others have argued that methodologically sound placebo-controlled trials, where participants are not exposed to excessive risks of harm, are ethical and that equipoise in this context does not provide an adequate ethical framework [30, 34].

Article 29 of the Declaration of Helsinki (issued in October 2000) states: "The benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic or therapeutic method exists" [5]. This article was initially interpreted by some, in its strictest sense, to mean that the use of placebo controls was ruled out whenever an effective therapy was available. In 2002, the WMA added a note of clarification to Article 29, reaffirming "its position that extreme care must be taken in making use of a placebo-controlled trial and that in general this methodology should only be used in the absence of existing proven therapy. However, a placebo-controlled trial may be ethically acceptable, even if proven therapy is available, under the following circumstances:

- Where for compelling and scientifically sound methodological reasons its use is necessary to determine the efficacy or safety of a prophylactic, diagnostic or therapeutic method; or
- Where a prophylactic, diagnostic or therapeutic method is being investigated for a minor condition and the patients who receive placebo will not be subject to any additional risk of serious or irreversible harm" [5].

The CIOMs guideline 11 [12] elaborates on these points, further stating that a placebo control can be used "when withholding an established effective intervention would expose subjects to, at most, temporary discomfort or delay in relief of symptoms." Examples cited include a slightly raised blood pressure or serum cholesterol, common headache, or treatments for baldness or common cold.

In relation to the term "compelling and scientifically sound methodological reasons," it has been argued that the use of "active controls" does pose methodological concerns [35, 36]. Such views would hold that a noninferiority or equivalence study showing no difference between a study drug and active comparator could be interpreted to mean that both were effective, both were ineffective, or the trial (for whatever reason) was simply not able to detect a difference between them. In this regard it has been noted that, in several areas of medicine, not all "known" active treatments will reliably prove to be superior to a placebo in every study. This particularly applies to analgesics, antidepressants, antianxiety drugs, antihypertensives, antiangina drugs, anti–heart failure drugs, antihistamines, and drugs for asthma prophylaxis [35]. Moreover, trials designed to demonstrate that a new drug and an active control possess similar efficacy do not provide sponsors and investigators with the same "built-in incentives for trial excellence" [19] as studies designed to show a treatment difference. It is relatively easy for poorly designed and conducted studies to fail to show a difference between treatment arms. Thus, for some therapeutic areas, it is widely considered that reliable evidence of efficacy can only be obtained by superiority trials or the internal validation of active-comparator equivalence or noninferiority trials using a placebo. In the former case, the requirement to demonstrate superior efficacy over an authorized treatment may be considered too restrictive. Moreover, an active comparator trial may expose patients to risk and fail to deliver a clear-cut answer.

Thus, if invoking this clause to justify inclusion of a placebo control, the possibility of "additional risk of serious and irreversible harm," including the period of time a placebo treatment may be administered, needs to be carefully considered. All other ethical safeguards should apply to placebo-controlled trials including ethical and scientific review, full disclosure and informed consent, and the right to withdraw at any time. Additional strategies to minimize the risk of participants include the incorporation of predefined "stop" rules in the study protocol and the monitoring of data collected during the study by a Data Safety and Monitoring Board (Chapter Monitoring). Where appropriate, interim analyses should be undertaken to ensure trial participants are not exposed to the placebo for any longer than necessary or to assess the likelihood that the trial will deliver a clear-cut answer. If, in the latter case, this probability is low, the trial should be terminated. Study designs that seek to address the ethical and practical issues associated with the conduct of placebo-controlled trials are described in the International Conference on Harmonisation (ICH) guideline "Choice of Control Group and Related Issues in Clinical Trials" [19], including "early escape" and "randomized withdrawal" designs.

### 6.4 Informed Consent

Informed consent is a central tenet of clinical research. It is fundamental to all codes of ethical clinical research. The first principle of the Nuremberg Code states that "the voluntary consent of the human subject is absolutely essential" [6]. The

Declaration of Helsinki (Articles 20–26) clearly addresses the principles of informed consent, including reference to subjects who may have a dependent relationship with their physician, subjects who are legally incompetent or physically and mentally incapable of giving consent, and subjects with a condition that renders them unable to give informed consent. In obtaining consent, clinical researchers should adhere to the requirements outlined in the ICH "Guideline for Good Clinical Practice" (Section 4.8) [37], the CIOMS guidelines 5 and 6 [12], and any additional codes published by regulatory authorities (e.g., 21 CFR 50) [38].

Consent must be voluntary and based on sufficient information about the proposed study and the implications of participation to allow potential trial participants to make an autonomous decision whether or not to enroll. The Belmont report states that "no undisclosed risks may be more than minimal" [11]. Importantly, subjects must have realistic expectations as to the study outcomes, including any potential benefit to both the individual participant and society. The language used on the informed consent documents should be "as non-technical as practical and should be understandable to the subject or the subject's legally acceptable representative and the impartial witness, where applicable" [37]. It is important that the informed consent process continue throughout the course of the study [12].

The source of funding, financial relationships, and financial interests of the parties involved should be disclosed in line with the recommendations in the FDA guidance "Financial Relationships and Interests in Research Involving Human Subjects: Guidance for Human Subject Protection" [39] or local institutional policies. This FDA guidance further recommends that, if a potential or actual financial conflict of interest exists that could "influence the tone presentation or type of information presented during the consent process," then a third party who has no conflict of interest should be involved in the consent process.

***Coercion and Inducement*** Coercion and undue inducement are ethically unacceptable and can invalidate consent. While the issue of patient dependence is addressed in Article 23 of the Declaration of Helsinki, researchers should be alert to the fact that more subtle forms of coercion (or intimidation) can result from the position of authority held by an investigating clinician. Indeed, in one study of patients consenting to a major surgical procedure, consent was based more on the trust rather than an assessment of information provided to them [40]. All subjects should be assured that a decision whether or not to participate in the proposed clinical trial will not affect their medical care [12].

It is generally accepted that, for studies that aim to recruit patients into later phases (phases II and III trials), financial reimbursement should only compensate for direct costs of participation (such as travel to and from the clinic). Exceptions to this position may be considered in situations where administration or outcome-testing schedules cause significant inconvenience or when little or no benefit is expected to result from trial participation.

In the case of phase I trials, bioequivalence or pharmacokinetic studies, where participants receive no medical treatment that may be of benefit, a payment above out-of-pocket costs as compensation for inconvenience can be offered. However, such a payment should not be so great as to encourage participants to expose themselves to excessive risk. Moreover, payment contingent on completion of the trial

may prevent participants from leaving a study against their better judgment and could be deemed to constitute undue inducement.

Reasons for leaving a trial should be documented. In cases of withdrawal due to adverse reactions to the study drug, trial subjects should be encouraged to fully articulate all reasons for leaving the trial, and full payment should be offered. Subjects who withdraw due to personal reasons should be considered for a prorated payment. Willful noncompliance on the part of a participant, resulting in expulsion from the study, may be grounds for withholding all payment.

Any incentives offered to trial participants must be reviewed by an ethics committee before recruitment activities commence (see the Declaration of Helsinki, Article 13).

One interpretation of inducement deserves further comment. Although the benefits of participation in clinical trials have been discussed by several authors [20, 31, 32], the prospect of improved medical care cannot be offered as inducement to participate in a trial. However, application of this ethical principle in the context of (for example) teaching hospitals that service populations who may not have access to or cannot afford ongoing quality medical care presents several ethical challenges [18]. Does the prospect of access to medical care (including, e.g., transport to and from the clinic) constitute undue inducement? Does the recruitment of such individuals raise issues of distributive justice that would require the burdens and benefits of clinical research to be evenly distributed (see CIOMs guideline 12 [12])? Does participation in a trial by those seeking access to treatments not otherwise available to them constitute exploitation? In considering these issues, clinical researchers should be cognizant of the principles of justice implicit in relevant articles in the Declaration of Helsinki. In particular, Article 19 states: "Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research." It is noted here that the definition of "populations" is open to interpretation, and there are many clinical research situations where the intended benefit is directed at the wider community. Further, Article 22 states: "The subject should be informed of the right to abstain from participation in the study or to withdraw consent to participate at any time without reprisal." Lastly, in relation to posttrial access of beneficial medicines, in its clarification to Article 30 of the Declaration of Helsinki, the WMA "hereby reaffirms its position that is necessary during the study planning process to identify post-trial access by study participants to prophylactic, diagnostic and therapeutic procedures identified as beneficial in the study or access to other appropriate care." This article raises several ethical and practical issues; importantly, posttrial access arrangements should be agreed to prior to commencing the study and such arrangements require prior review by an ethics committee. For a discussion of the wider ethical issues of research in populations or communities with limited resources, the reader is referred to CIOMS guidelines 10 and 11 [12].

***Competence*** Consent should be given by competent individuals with the capacity to understand the information provided to them. It is recognized that conditions for informed consent may vary with the nature of the study and the cultural and religious sensitivities of the participants and their communities. The Belmont report states: "it is necessary to adapt the presentation of the information to the subject's capacities" [11]. It is important that the ethical review process (see Chapter Methods

of Randomization) provides a further level of protection to the informed consent process. The ICH "Guideline for Good Clinical Practice" [37] requires that, before initiating a trial, the investigator must have obtained "written approval of the informed consent form and any other written information to be provided to subjects." Further, consent by a subject alone is not reason enough to justify participation in the trial. The Declaration of Helsinki (Article 15) states: "The responsibility for the human subject must always rest with a medically qualified person and never rest on the subject of the research, even though the subject has given consent."

Despite the best attempts of sponsors and investigators to clearly present information about a clinical trial to potential participants, several studies have shown that some degree of communication difficulty is inevitable [21]. For example, the concept of randomization and its justification may not be fully grasped by all individuals [29, 41], and patients who have recently received a diagnosis of a life-threatening disease may not be in a psychological state that enables them to absorb all the information provided to them [42]. In this context, provision of information should not be conducted in a manner that may cause distress; "respect for persons" does not only equate with autonomy [11, 43]. The degree of protection provided by investigators and IRB/Institutional Ethics Committees (IECs) should take into account both a patient's capacity for self-determination and the risk of harm and degree of benefit that participation in a clinical trial may entail.

Finally, all investigators and sponsors should carefully review their patient information sheets and informed consent forms before initiating their study. Are all risks adequately disclosed? Is the language in any way coercive? Are the chances of receiving a placebo treatment or active therapy fully spelled out? Are financial conflicts of interest disclosed? On a more operational note, Good Clinical Practice (GCP) audits commonly reveal shortcomings in the informed consent process, including use of outdated forms or forms that have not been approved by the relevant ethics committee, timing of signing of the informed consent form in relation to commencement of trial procedures, and forms not appropriately signed or dated by the subject or witness.

### 6.5 Transparent Clinical Trial Culture: Financial Disclosure, Trial Registration, and Reporting of Results

Several related initiatives that seek to increase the transparency of the clinical trials process have arisen in response to (1) concerns that financial interests in clinical research may be placing trial participants at risk [44]; (2) the delayed disclosure or nondisclosure of trial results and publication bias [45], including selective publication [46], selective reporting [47], and inadequate reporting [48]; and (3) inappropriate authorship and ghost writing of publications [49]. There is little doubt these concerns have significant ethical implications and momentum is building on several fronts to address them.

***Financial Disclosure*** Clinical researchers should be aware of and adhere to the ethical codes and guidance documents relevant to both their regulatory territories and institutional affiliations. The Declaration of Helsinki (Article 13) states: "The researcher should also submit to the (ethical review) committee, for review, information regarding the funding, sponsors, institutional affiliations, other potential conflicts of interest and incentives for subjects."

The document "Financial Relationships and Interests in Research Involving Human Subjects: Guidance for Human Subject Protection" was released by the DHHS in 2004 to help research institutions, IRBs, and investigators identify potential and actual conflicts of interest and suggest means to eliminate or manage such conflicts with the interests with the welfare of the trial subjects in mind. This guidance document, which is based on the ethical principles described in the Belmont report (respect for persons, beneficence, and justice), poses several questions that IRB members, investigators, and researchers should consider when determining whether or not a conflict of interest exists; it then suggests several "actions to consider" in each case. Many research institutions have adopted these principles.

It should be noted that some consider that the requirement for investigators to disclose any actual or potential conflicts of interest on the informed consent documents does not go far enough to adequately protect research subjects. Indeed, there is a lack of data on how potential clinical trial participants use disclosures in their decision-making process [44]. Moreover, disclosure alone, without further safeguards, may even confer a "moral license to exaggerate" on the part of investigators that could potentially increase any bias in the study that exists as a result of a conflict of interest [43]. Some therefore propose that additional mechanisms must be found to protect subjects; in many cases, the only answer would seem to be to encourage investigators conducting a trial to divest any possible conflicts of interest.

***Registration of Clinical Trials*** The participation of any subject in a clinical trial that does not contribute to the medical knowledge of the wider research community contravenes the obligations of clinical researchers. Nondisclosure or delayed disclosure of trial results may mean that the welfare and safety or trial participants could be adversely affected by subsequent clinical trial designs and ethical review processes that do not build on prior research knowledge. On a wider scale, failure to consider all available data may misdirect those responsible for health policy decisions and resource allocation. The Declaration of Helsinki includes several statements relevant to these considerations:

*Article 16* "Every medical research project involving human subjects should be preceded by careful assessment of predictable risks and burdens in comparison with foreseeable benefits to the subject or to others.

The design of all studies should be publicly available."

*Article 11* "Medical research involving human subjects must ... be based on a thorough knowledge of the scientific literature, other relevant sources of information. ..."

*Article 19* "Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research."

Registration of clinical trials on publicly available databases represents a key mechanism to promote transparency, knowledge sharing, and the timely and accurate disclosure of clinical information. A global movement for registration of clinical trials is gaining momentum, driven by bodies such as the Ottawa Group [50, 51], WHO [52], and the International Committee of Medical Journal Editors (ICJME)

[53, 54] (see below) and the trial registries. Many trial registries currently exist, including the International Standard Randomized Controlled Trial Number (ISRCTN) register and ClinicalTrials.gov, which is administered by the National Library of Medicine. The WHO International Clinical Trials Registry Platform (ICTRP) project aims to set international standards for trial registration, ensure a minimum set of results are reported, and provide global trial identification and search capability. The ICJME policy, requiring trial registration as a prerequisite to publication, has resulted in a marked increase in the number of trials registered [15, 54].

However, registration of trial information does not currently require that trial outcomes will be disclosed and there are no international standards for reporting of clinical trial results [55]. In response, many now advocate systems to facilitate full public disclosure of published and unpublished trial results. Significantly, in the United States, both federal and state legislation are addressing such concerns. In Maine, a law that came into effect in October 2005 requires companies wishing to advertise prescription drugs to disclose trial results, including adverse effects. In addition, federal legislation currently under consideration will require reporting of results in government databases [15]. For example, the Fair Access to Clinical Trial Act of 2005 would see the ClinicalTrials.gov database expanding to include a clinical trials registry and clinical trials results.

Significant challenges to the registration of clinical trials and disclosure of results lie ahead, including agreement between the pharmaceutical industry and other stakeholders as to the minimal data set for trial registration [51], validation of the registry data, prevention of duplicate registrations, and defining and naming of interventions and the format of reporting and validation of results [15]. Nevertheless, the climate is changing. As noted by a recent ICMJE editorial, "three years ago trial registration was the exception; now it is the rule" [54].

***Publication of Clinical Trial Results*** "Both authors and publishers have ethical obligations. In publication of the results of research, the investigators are obliged to preserve the accuracy of the results. Negative as well as positive results should be published or otherwise publicly available" (Declaration of Helsinki, Article 29).

In addition to the registration of trial information and initiatives under way to promote the public disclosure of trial results, several important policy and guidance documents have been developed by professional bodies to promote the quality of reporting of clinical trials in biomedical journals.

*International Committee of Medical Journal Editors* Three policy initiatives of the ICMJE, a committee representing 12 member biomedical journals, are discussed below. These include the requirement to register trials as a prerequisite to publication and requirements for authorship and disclosure of any conflicts of interest on published manuscripts. Additional information can be found in the Uniform Requirements for Manuscripts (URM) Submitted to Biomedical Journals, a set of ethical principles and recommendations developed by the ICJME to promote the accurate reporting of biomedical studies [56]. These guidelines have been adopted by many journals.

1. *Requirement to Register Trial: Prerequisite to Publication* In 2005 the ICMJE established a policy that requires information about trial design to be prospectively registered in recognized databases as a prerequisite to publication in member journals as follows [53]:

> The ICMJE member journals will require, as a condition of consideration for publication, registration in a public trials registry. Trials must register at or before the onset of patient enrollment. This policy applies to any clinical trial starting enrollment after July 1, 2005. For trials that began enrollment prior to this date, the ICMJE member journals will require registration by September 13, 2005, before considering the trial for publication.

A marked increase in the number of registrations lodged with the five recognized registries was seen around the time of implementation of the policy. The largest existing registry, ClinicalTrials.gov, which registered around 30 trials per week before September 2005, received over 200 registrations per week after September 2005 [15]. The number of registrations continued to grow as many other biomedical journals embraced this policy.

Although early-phase studies (including phase 1 trials and pharmacokinetic studies) were initially excluded from this requirement [53], the ICMJE has recently adopted the WHO definition of clinical trials as "any research study that prospectively assigns human participants or groups of humans to one or more health-related interventions to evaluate the effects on health outcomes" [54]. Thus, as of July 1, 2008, all early-phase studies will require, as prerequisite to their publication, registration on a recognized database. Importantly, in addition to the five previously recognized registries, the ICJME will now accept registration on primary registries participating in the WHO ICTRP project [54].

2. *Requirements for Authorship* The URM lists three requirements for authorship as follows [56]:

- Substantial contributions to conception and design, or acquisition of data, or analysis and interpretation of data
- Drafting the article or revising it critically for important intellectual content
- Final approval of the version to be published

Authors should meet all these conditions and no authors who fulfill these criteria should be omitted. The URM further states that "acquisition of funding, collection of data, or general supervision of the research group, alone, does not justify authorship." While these guidelines have been widely adopted, the requirements of individual journals should be observed.

3. *Conflict of Interest* In-line with the Declaration of Helsinki (Article 27), which states, "Sources of funding, institutional affiliations and any possible conflicts of interest should be declared in the publication," the URM requires: "When authors submit a manuscript, whether an article or a letter, they are responsible for disclosing all financial and personal relationships that might bias their work. To prevent ambiguity, authors must state explicitly whether potential conflicts do or do not exist." Again, individual journals often have their own conflict of interest policies.

*Good Publication Practice (GPP) for Pharmaceutical Companies* The GPP guidelines set forth principles that aim to increase the transparency of the processes

involved in the publication of industry-sponsored trials, reduce publication bias, and clarify the roles of the sponsor company and academic investigators [57, 58]. The guideline includes topics such as publication standards, premature publication, duplicate publication, authorship, and the role of professional medical writers.

A further comment on the role of professional medical writers is made here. Ghost writing occurs when a professional writer controls the content of the manuscript and discloses neither their involvement nor their funding source. This is ethically unacceptable. However, working with a professional medical writer should pose no ethical concerns provided that (1) the medical writing assistance is acknowledged and (2) their source of funding is disclosed [59]. Throughout the writing of the manuscript, authors should maintain responsibility and control for the content of the publication, including key messages and data to be presented.

*CONSORT (Consolidated Standards of Reporting Trials) Statement* The CONSORT group (which comprises trialists, methodologists, and medical journal editors [60]) has developed several initiatives to improve the reporting of randomized clinical trials, including the CONSORT statement. The CONSORT statement is an evolving guideline that was originally published in 1996 [61] and revised in 2001 [48]. Following a meeting of the CONSORT group in January 2007, a further update of the CONSORT statement is due for release. The latest versions of all CONSORT documents can be found on the CONSORT group website [60].

In its current form, the CONSORT statement includes a 22-item checklist and flow diagram that is intended to improve the quality of the writing and assist in the review and evaluation of RCT reports. In particular, the checklist items encourage transparency in the reporting of the trial methods and results, which together account for 17 of the 22 items. The flow diagram depicts the number of participants progressing through the enrollment, intervention allocation, follow-up, and data analysis stages of a clinical trial, allowing the reader to evaluate the basis of any analysis undertaken. Although the main CONSORT statement is directed at two-group parallel RCTs, extensions to the statement address alternative trial designs, including cluster trials [62] and noninferiority and equivalence randomized trials [63]. A checklist of items that should be included in conference or journal abstracts is due for publication in 2007 [60]. It is highly recommended that the requirements of the CONSORT statement be considered early in the trial design process.

## 7 ETHICALLY CHALLENGING SCENARIOS IN CLINICAL RESEARCH

### 7.1 Children

Children, by virtue of their developmental and cognitive abilities, are a vulnerable population in relation to research participation. The Willowbrook Hepatitis Study [2] and many other similar questionable pediatric research studies have shown us that unscrupulous researchers have resorted to the use of children in research trials because they were seen as easy to recruit and manipulate. With the advent of the Nuremberg Code, which required informed consent, research in children declined because it was seen as almost impossible to get fully informed consent from a child of limited cognitive ability. For this reason and the fact that pharmaceutical manu-

facturers saw pediatric markets as too small to warrant expensive pediatric clinical trials, the majority of medications in clinical use today have not been properly tested in children but are being used "off label." This in itself is a major ethical dilemma as several important differences in disease pathophysiology, pharmacokinetics, pharmacodymanics, and adverse drug reactions occur between children and adults. For example, the effective dose of a single application of an asthma nebulizer will be higher in an adult with effective hand/breathing coordination than a relatively uncoordinated small child. The ability of diazepam to cause sedation in adults but agitation in some children is an example of the wildly varying physiological responses to a drug. The absence of adequate studies in the pediatric population hinders the effective provision of the medical care of children. As such, there has been a recent push by U.S. and European regulators to require drug manufacturers to assess the safety and effectiveness of medications in pediatric patients when pediatric use is anticipated [64, 65]. The U.S. Best Pharmaceuticals for Children Act—2002 creates financial incentives for pharmaceutical companies to engage in pediatric research by allowing a 6-month extension to their exclusive patent protection and funding for research of drugs that no longer have patent protection.

While distributive justice mandates that research should be conducted on children to enhance their health care, there are some instances when it is absolutely inappropriate to conduct research on children [66]. It is ethically appropriate to exclude children from research when:

(a) The research topic is irrelevant to children (e.g., ischemic heart disease, alzheimer's disease).
(b) Existing data in adults are sufficient to judge risks in children.
(c) Local laws or regulations bar inclusion of children in this type of research.
(d) A nontherapeutic study which places a child at greater than small increase in minimal risk. Minimal risk is defined as a risk that is "greater than those already encountered in daily life or during the performance of routine physical or psychological examinations or tests." The FDA, DHHS, and National Institutes of Health (NIH) have produced guidelines on categories of risk in pediatric research and the associated approval requirements [66]. While the degree of risk associated with "routine life" is open to varying interpretations by individual IRBs, it would generally be considered unethical to expose healthy children to any material risk of a serious adverse outcome, such as a phase I study of a new class of drug.

Pediatric research raises two potential dilemmas above and beyond the ethical dilemmas routinely seen in adult research [65–67]:

(a) *Informed Consent* Informed consent, a process where research participants are given sufficient information about a study to allow them to determine if it the risks and benefits warrant their own involvement, is not possible for a child with limited cognitive powers below the legal age of "consent." Pediatric research therefore requires a two-part consent process—parental permission and the child's assent. Central to the requirement of parental permission is the assumption that a loving, protective relationship exists between the

parent/guardian and the child. This assumption has two weaknesses. First, the theologian Paul Ramsey [68] states that a parent does not have the moral authority to permit a child to be put at risk of harm in an experiment from which the child could not benefit medically as a child is not a piece of property but an autonomous individual. Second, in dysfunctional relationships the parents may not always have the child's best welfare at hand. Therefore, if the researcher has any suspicion of a dysfunctional relationship between child and parent, they should defer any decisions concerning that child's participation to an independent IRB. After a parent has given permission for their child to be involved in research, the child's assent must be sought. The child should be given a simple explanation about why the research is being conducted and what procedures and discomfort may occur if they are to be involved. Researchers also need to define risks with the child's perspective in mind, not that of an adult. For example, separation from parents and unfamiliar surroundings may be considered a risk from the perspective of a child but not an adult. Assent should be sought apart from the parents' direct influence and the child must be informed that it is their right to refuse involvement. While childhood assent is always preferable, there are several instances where it is not mandated. For example, assent is not required if the child's capacity to understand the research is limited (intellectual age of less than 7 years, American Academy of Pediatrics) or the potential direct benefit to the heath of the child is high and only available through direct participation in the research (e.g., new chemotherapy for a childhood cancer). Apart from these limitations, failure to obtain a child's assent overrides a parent's permission and prohibits that child's involvement in research.

(b) *Payment for Research Participation* Payment to pediatric research participants becomes particularly problematic because of the child's vulnerability and dependence on their parents as the primary decision makers. Poor families are particularly vulnerable to monetary rewards, and therefore offering large financial incentives may create unnecessary coercion by the parents for their children to participate in research. Only small token gestures of appreciation or reimbursement of direct costs of involvement should be made to ensure payment is not the reason parents are enrolling their children in the research. Furthermore, incentives given to children should not be excessive and, according to American Academy of Paediatrics guidelines [69], should only be revealed after enrollment so that the child's participation is voluntary. This however is contrary to usual informed consent guidelines where incentives should be discussed before enrollment. A reasonable compromise may be to mention in the consent process that a gift will be given to participants without outlining its exact nature.

### 7.2 Mentally Impaired

Over the last 50 years very effective pharmacological treatments for mental disorders such as depression, psychosis, bipolar disorder, and obsessive-compulsive disorder have seen the transition of mental health care from institutions to the general community, resulting in huge benefits to patients and society in general. Without research, none of these life-changing benefits would have materialized.

Guideline 15 of the International Ethical Guidelines for Biomedical Research Involving Human Subjects [12] states that research on mentally impaired individuals is permissible provided that the purpose of the research is to obtain knowledge relevant to the particular heath needs of the mentally impaired and that the research cannot be equally well carried out on persons with full mental capacity.

According to Michels [70] the conduct of clinical research in mentally ill patients raises three key ethical questions. Are mentally ill subjects especially vulnerable to exploitation? Are they competent to give informed consent? Are psychiatric research methods particularly dangerous? Following the suicide of a patient with schizophrenia after being asked to cease their antipsychotic medication in the "wash out" period of a clinical trial, regulators have been struggling with the ethical dilemma of whether mentally ill patients should be allowed to participate in research. The U.S. National Bioethics Advisory Commission (NBAC) and DHHS have both published guidelines regarding the ethical conduct of clinical research in mentally ill patients [71, 72]. A summary and discussion of these recommendations are presented below:

(a) *Impaired Capacity* According to the NBAC, mental capacity to consent to research requires that the subject understand the difference between treatment and research, the nature of the research being conducted, its risks and benefits, available alternatives, and the fact that he or she is making a decision and that this decision can be changed. The subject must not be swayed by a pathological affective state, a false belief, or a dependent relationship that might interfere with the decision or his or her autonomy and must be capable of making a stable, reasoned choice and communicating it. It should be noted that merely having a mental illness does not mean that an individual's mental capacity to give informed consent is impaired. Different mental illnesses have varying effects on a person's decision-making capacity. Furthermore, illnesses such as schizophrenia can produce fluctuating levels of capacity as an individual passes through stages of good and bad mental heath. It is therefore advisable that researchers carefully consider the timing of recruitment of participants into research studies to avoid periods of heightened vulnerability due to acute mental illness. Furthermore, while not yet mandated, it may be preferable to get an independent expert in mental health to assess a potential research subject's capacity to give informed consent, especially if this research places a participant at more than minimal risk. Finally, as informed consent is a continual process, a research participant's capacity to consent should be continually monitored throughout the entire life of the study, preferably by an independent monitor.

(b) *IRB Provisions* Under U.S. regulations, IRBs that regularly review research involving vulnerable persons should have one or more individuals on that IRB who are expert within the field. In the area of mental health research it has been suggested that an expert in the area of mental health research and an individual from a relevant mental health support group would provide the best assessment of research protocols and therefore protection of research participants.

(c) *Surrogate Permission* Where permitted by law, individuals with impaired capacity may have a family member or other legally authorized representa-

tive serve as a surrogate for research decisions. Surrogates should be informed of the risks, benefits, and alternatives to the research when they are providing permission. The surrogate should be educated that it is their duty to first act in a manner that reflected the views of the mentally incapacitated individual while they were decisionally capable (substituted judgment). If the values of the individual are unknown, a "best interest" standard should be used. The autonomy of the patient should be respected and therefore their assent to participation in research should be obtained whenever possible. Their right to withdraw from research should be respected unless the research treatment may be in the best interests of the mentally incapacitated patient and not available outside of a research setting.

### 7.3 Women and Pregnancy

Prior to the 1990s women were systematically excluded from participating in research studies primarily because of the fear that unrecognized pregnancy might place the early embryo at risk, increasing liability risk for researchers. Such a policy of exclusion is not just since it leads to an unequal knowledge base regarding the correct use of medications in the male and female population, potentially reducing the quality of clinical care provided to women. Differences in body composition (fat to muscle ratio), hormone fluctuations during the menstrual cycle, and changes in physiology specific to pregnancy make it highly likely that significant differences in pharmacokinetics and pharmacodynamics exist between the two sexes, therefore mandating more balance research protocols [73].

Guideline 16 of CIOMS International Ethical Guidelines [12] states that the potential for becoming pregnant during a study should not in itself be used as a reason for precluding or limiting participation. A paternalistic approach where an investigator, sponsor, or IRB limits a woman's capacity to be involved in research because of a potential risk to the fetus infringes a woman's autonomy. McCullough [74] argues that a previable fetus does not have the moral or legal status of an autonomous individual and as such a woman should have the absolute right to make an autonomous decision concerning her own involvement in potentially harmful research without regard for the well-being of a nonviable fetus. However, in order to sensibly minimize risk to a potential unborn child, ethical guidelines mandate two precautions when conducting research in women of reproductive age [75]. First, research participants should be screened for pregnancy with sensitive and reliable pregnancy tests before enrolment if their participation in the research poses more than a minimal risk to the fetus or if being pregnant may materially increase their own risk during the conduct of the study. Second, researchers should guarantee access to effective contraceptive methods before enrollment in research. Research protocols should not mandate certain types of contraceptive use (e.g., IUCD, contraceptive pill) and respect the women's autonomy to choose a method, including abstinence, according to her own needs and values.

Clinical research on pregnant women carrying a potentially viable fetus (post 23 weeks gestation) is a larger ethical dilemma as here the fetus is an individual by virtue of its ability to survive ex utero. A general prohibition of termination of pregnancy beyond the period of potential viability provides legal support for this moral concept that a fetus's own heath must be considered when conducting research

on women in the later stages of pregnancy. McCullough [74] outlines four criteria for the ethical conduct of phases I–II studies in pregnant women:

(a) The medication should be reliably predicted to alter the course of pregnant women's condition based on prior animal and human studies.
(b) Previous animal and/or human studies have documented no deaths or serious or irreversible injury to pregnant women that was caused by the medication.
(c) Previous animal and/or human studies have documented no deaths or serious or irreversible injury to the fetus that was caused by the medication.
(d) Previous animal and/or human studies have reported no or only a very low risk of less serious injury to the fetus that was caused by the medication.

Pregnant women should be provided with adequate information regarding the known benefits and risks of research to their own health and that of the fetus to ensure adequate informed consent. Appropriate follow-up of heath outcomes of children exposed to an investigational agent during pregnancy should also be arranged to confirm that the investigational agent is not harmful to the fetus.

Consent of a pregnant woman alone is usually sufficient for most research which may have an impact on the fetus. In the United States 45 CFR 46 states that "when research holds out the prospect of direct benefit solely to the fetus then the consent of the pregnant woman and the father should be obtained." However, international guidelines such as CIOMS [12] and the American College of Obstetricians [73] do not support this need for paternal consent as paternal rights may weaken or infringe maternal autonomy—the right of a woman to take action in decisions that affect her own body and heath. At present, the need for maternal, not paternal, informed consent is standard ethical practice in medical research.

### 7.4 Critically Ill Patient

Clinical research involving critically ill patients is necessary to reduce the extreme morbidity and mortality encountered in the intensive care unit (ICU). However, this type of research is ethically challenging for two principal reasons [76]. First, critically ill patients are captive and thus vulnerable as they are dependent on the ICU team for all aspects of care or even life itself. This vulnerability raises concerns about the patient or their surrogate's ability to give informed, autonomous consent to participate in clinical research, even if they can judge the pros and cons of participation. Second, most critically ill patients lack decisional capacity due to their illness (head injury, delirium, and drug-induced coma) or the drugs (sedatives, analgesics) that they are receiving. As a result, their family members are usually asked to provide permission for research participation. While a recent study concerning research in the ICU suggests that surrogates do predict the choices of patients with a reasonably high degree of accuracy [77], there is the potential for a surrogate to make a decision that ultimately contravenes the participant's real wishes.

At the present moment there is no legislation in place governing research in the setting of the critically ill patient. The American Thoracic Society [78] and the American Heart Association [79] have published some very useful guidelines concerning involvement of critically ill patients in clinical research. These guidelines

mirror issues discussed in previous paragraphs related to research in vulnerable persons such as the mentally ill. However, we will outline some potential solutions specific to the ICU setting:

(a) *Separation of Clinical and Experimental Team* Due to the extreme vulnerability of the critically ill patient and their dependence on the ICU team, it is probably best that researchers separate from the clinical team ask patients or their surrogates for permission to be involved in any study. This ensures that patients/surrogates do not confuse research with therapeutic intent and can feel free to refuse involvement without any perceived pressure that such refusal may harm the standard of routine care being provided to the patient.

(b) *Consent* As most patients are not in a position to give their own consent, it is permissible for family members to provide surrogate consent provided that the research is of minimal risk or may have some direct benefit to the patient. It is probably unethical to allow a surrogate to make a decision regarding a third person (the patient) that places that individual at more than minimal risk. Alternatives to the use of surrogate consent include retrospective consent, prospective consent, and waiver of consent by the IRB. An example of retrospective consent would be when a small sample of blood is taken as part of routine clinical care and then stored for potential later use in research once the patient has recovered and given consent. In prospective consent a noncritically ill patient is consented for research in the event that he or she may become critically ill later. For example, preoperatively a patient undergoing major surgery may be consented to research on a new therapy to prevent lung infections related to prolonged artificial ventilation in the ICU. Finally, in limited studies on true emergencies where the intervention is minimal, an IRB may waive the need for patient or surrogate consent. For example, a randomized trial between a manual CPR technique and a new but FDA-approved mechanical CPR machine may be undertaken without consent as both are reasonable care and there is no time for consent in a cardiac arrest [29].

### 7.5 Research in Undeveloped World

The conduct of clinical research in undeveloped countries raises three principal ethical concerns [80, 81]. First, many individuals from the undeveloped world have only very basic education, making it difficult for them to understand abstract concepts such as placebos, making informed decisions on the benefits and disadvantages of research involvement difficult. Furthermore, health care expenditure in the undeveloped world is paltry compared to western society, with even basic medical care often lacking. If an individual has the chance of receiving some medical treatment in the form of a trial medication, compared to no chance of medical care outside of a research protocol, does this really allow for an autonomous unpressured decision? For these reasons it is potentially more difficult to obtain truly informed consent in the undeveloped world.

The second major ethical issue surrounding research in the developing world is exploitation of communities that are unlikely to benefit themselves from the medical

advances developed by the research. Guideline 10 of the CIOMS ethical guidelines [12] states that "research must be responsive to the needs and the priorities of the population or community in which it is carried out." Furthermore, the guideline goes on to state that "any intervention or product developed, or knowledge generated, must be made reasonably available for the benefit of that population or community." It is only just that a community that may potentially be harmed by research should also share in its final benefits (new proven therapy). Unfortunately this has not always been the case. For example, the AIDS Clinical Trials Group protocol 076 was a study in which pregnant women from the undeveloped world were randomized to receive either placebo/routine care or oral antiviral medication throughout pregnancy, intravenous antiviral during labor, and postpartum oral antiviral for the baby in order to determine if such intensive treatment could reduce the vertical transmission of HIV to the child. While this trial did show a very significant reduction in vertical transmission, it was heavily criticized as unethical because the proposed treatment is unlikely to ever be reasonably available to mothers in the third world because of significant cost. The trial protocol cost $800 per woman and child, 600 times the annual per-capita allocation for heath care in Malawi [82]. As such, while proven to be an effective therapy for women in the western world, the results of the trial are unlikely to ever be practically applicable to the community in which the information was gained, making the study exploitative and unethical. Clinical trials can only be ethically performed in the developing world if the pathology in question is clinically relevant to the developing community and the trial intervention, if proven to be effective, is likely to be reasonably available to the community after completion of the research.

The final ethical concern for research in the developed world is an appropriate choice for the "alternative" control treatment in a trial. Some commentators suggest that it is ethical to use a placebo in a clinical trial in the undeveloped world, as no treatment is the default "standard of care" present in these poor countries [83]. These individuals suggest that since half the participants will be exposed to a potentially useful study medication, the "greater good" is still being done, making the study ethical. However, the majority view is to the contrary. The CIOMs guideline [12] states that research participants in the control arm of a trial should receive an established effective intervention (guideline 11). The use of a placebo is only ethically justifiable if there is no established effective intervention or delaying the use of this established intervention would not add any serious risk or cause any irreversible harm. As the CIOMs Guideline 11 states [12], "An economic reason for unavailability of an established effective intervention cannot justify a placebo-controlled study in a country of limited resources when it would be unethical to conduct a study with the same design in a population with general access to the effective treatment outside the study." The reader is referred to the CIOMs Guideline for a wider discussion of this topic.

## 8 FOUR GOLDEN RULES OF ETHICAL CONDUCT IN CLINICAL RESEARCH

After consideration of the various philosophical theories related to medical ethics and review of the relevant published guidelines it is possible to summarize ethical

research practice into four guiding principles. These principals, or golden rules, are summarized by the acronym AIMS to help facilitate recall, where A refers to respecting patient autonomy, I stands for maximizing the potential impact of the research on society in general, M refers to the mitigation of potential harm to research participants, and S stands for maintance of scientific integrity in all aspects of clinical research. The following sections outline the key features of each of these golden rules.

### 8.1 A: Respect for Patient Autonomy

Researchers should respect an individual's right to make decisions regarding their future by providing them with information which honestly outlines the risks and benefits of participating in the research in terms that are easily understandable to the average lay person of limited education (informed consent). Researchers should avoid offering excessive financial or other incentives that may impede unbiased decision making on the part of the potential research participant. When a subject lacks the ability to make an informed decision themselves (child, mental incapacity), the researcher must gain informed consent from a legally authorized representative. Research participants must feel free to exit a study at any stage without fear of compromising their standard medical care. Research participants should expect the same degree of respect of their privacy and dignity as would be afforded patients undergoing standard medical care. Maintenance of individual participant's privacy during the conduct of the trial and in the publication of trial results is paramount.

### 8.2 I: Maximization of Research Impact on Medical Treatment

The impact of a piece of research on contempary medical understanding/treatment can be maximized by considering four issues. First, research protocols should be scientifically well designed so that they have the capacity to answer the question of interest. Poorly designed trials with clinically irrelevant endpoints, inadequate sample sizes, or inherent biases that make firm conclusions impossible are unethical as they consume scarce resources while placing participants at risk of adverse events for no real gain. Proper peer review and IRB assessment should prevent such studies from even commencing. Second, it is important that trials are not designed with very limited inclusion criteria (e.g., white, male, normal weight, 30–40 years age) as the results of these types of trials may not be applicable to the population in general. Justice requires that, if possible, a broad cross section of the community should be approached to be involved in research so that the potential benefits are equitably distributed throughout society. Third, it is a moral imperative that the results of research must be published within the scientific literature, irrespective of the research outcome. Failure to publish negative outcomes could create a situation where an identical study is replicated by an independent research group unaware of the original study outcome, thereby exposing the second group of research participants to unnecessary risk while wasting valuable research resources. Finally, researchers should only conduct experiments that have scientific and social worth and not use human beings in frivolous research.

### 8.3 M: Minimization of Risk to Research Participants

According to the theory of utilitarianism, it is ethically acceptable to expose an individual to justifiable risk provided the greater good is served. However, there is a moral obligation on the part of the researcher to mitigate risk by designing protocols that minimize risk or provide backup that reduces the consequences of an adverse event if it were to occur. For example, before conducting a phase I study investigating a new drug in healthy volunteers it is imperative that extensive testing in several different animal models has shown this investigational agent to be relatively safe. Furthermore, clinical trials should be supervised by appropriately trained and qualified medical personnel that are able to identify and treat any adverse reaction to a trial medication. The research should be conducted in a facility that has the appropriate equipment available to treat any medical complication of the research. Data-monitoring committees, independent of the research sponsor, should monitor trial data during the conduct of the trial to ensure the welfare of trial participants. These committees significantly enhance the safety of clinical research as they enable early termination of unsafe trials. Finally, it is a legal and moral imperative that all research participants are covered by insurance that will provide free medical care and compensation if they are inadvertently injured as a result of their participation in the research.

### 8.4 S: Scientific Integrity

Researchers have an ethical obligation to objectively analyze and report data. Improper data analysis or biased reporting of results in the scientific literature is unethical as it could lead to the adoption of medical treatments as standard proven therapy when in fact these treatments may be at best useless or worse even harmful. Careful analysis and recording of data, sharing of data and resources, and respect of research colleagues are all important components of ethical research conduct.

## 9 CONCLUSION

Our understanding of what constitutes ethical conduct in clinical research has come a long way since the advent of the Nuremberg Code in 1949. Today, the clinical researcher has several excellent guidelines [5, 11, 12] to help with the design and conduct of clinical studies that maximize participant safety and autonomy while still allowing appropriate scientific experimentation. This chapter has outlined the ethical principles used in the development of these clinical research guidelines. It is hoped that with an in-depth knowledge of these principles, researchers will be in a better position to design and conduct scientifically and ethically appropriate clinical trials. We hope that this chapter will facilitate a better understanding of ethical principles and the importance of ethics to clinical research practice.

## APPENDIX A NUREMBERG CODE*

1. The voluntary consent of the human subject is absolutely essential. This means that the person involved should have legal capacity to give consent; should be so situated as to be able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, over-reaching, or other ulterior form of constraint or coercion; and should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision. This latter element requires that before the acceptance of an affirmative decision by the experimental subject there should be made known to him the nature, duration, and purpose of the experiment; the method and means by which it is to be conducted; all inconveniences and hazards reasonable to be expected; and the effects upon his health or person which may possibly come from his participation in the experiment.

   The duty and responsibility for ascertaining the quality of the consent rests upon each individual who initiates, directs or engages in the experiment. It is a personal duty and responsibility which may not be delegated to another with impunity.
2. The experiment should be such as to yield fruitful results for the good of society, unprocurable by other methods or means of study, and not random and unnecessary in nature.
3. The experiment should be so designed and based on the results of animal experimentation and a knowledge of the natural history of the disease or other problem under study that the anticipated results will justify the performance of the experiment.
4. The experiment should be so conducted as to avoid all unnecessary physical and mental suffering and injury.
5. No experiment should be conducted where there is an a priori reason to believe that death or disabling injury will occur; except, perhaps, in those experiments where the experimental physicians also serve as subjects.
6. The degree of risk to be taken should never exceed that determined by the humanitarian importance of the problem to be solved by the experiment.
7. Proper preparations should be made and adequate facilities provided to protect the experimental subject against even remote possibilities of injury, disability, or death.
8. The experiment should be conducted only by scientifically qualified persons. The highest degree of skill and care should be required through all stages of the experiment of those who conduct or engage in the experiment.
9. During the course of the experiment the human subject should be at liberty to bring the experiment to an end if he has reached the physical or mental state where continuation of the experiment seems to him to be impossible.

*Reprinted from *Trials of War Criminals before the Nuremberg Military Tribunals under Control Council Law No. 10, Vol. 2, pp. 181–182*. Washington, DC: U.S. Government Printing Office, 1949.

10. During the course of the experiment the scientist in charge must be prepared to terminate the experiment at any stage, if he has probable cause to believe, in the exercise of the good faith, superior skill and careful judgment required of him that a continuation of the experiment is likely to result in injury, disability, or death to the experimental subject.

## APPENDIX B WORLD MEDICAL ASSOCIATION DECLARATION OF HELSINKI: ETHICAL PRINCIPLES FOR MEDICAL RESEARCH INVOLVING HUMAN SUBJECTS*

Adopted by the 18th WMA General Assembly, Helsinki, Finland, June 1964, and amended by the

29th WMA General Assembly, Tokyo, Japan, October 1975
35th WMA General Assembly, Venice, Italy, October 1983
41st WMA General Assembly, Hong Kong, September 1989
48th WMA General Assembly, Somerset West, Republic of South Africa, October 1996 and the 52nd WMAN General Assembly, Edinburgh, Scotland, October 2000

Note of Clarification on Paragraph 29 added by the WMA General Assembly, Washington 2002.

Note of Clarification on Paragraph 30 added by the WMA General Assembly, Tokyo 2004.

### A. Introduction

1. The World Medical Association has developed the Declaration of Helsinki as a statement of ethical principles to provide guidance to physicians and other participants in medical research involving human subjects. Medical research involving human subjects includes research on identifiable human material or identifiable data.

**Clarification of paragraph 29*: The WMA hereby reaffirms its position that extreme care must be taken in making use of a placebo-controlled trial and that in general this methodology should only be used in the absence of existing proven therapy. However, a placebo-controlled trial may be ethically acceptable, even if proven therapy is available, under the following circumstances:

- where for compelling and scientifically sound methodological reasons its use is necessary to determine the efficacy or safety of a prophylactic, diagnostic, or therapeutic method or
- where a prophylactic, diagnostic, or therapeutic method is being investigated for a minor condition and the patients who receive placebo will not be subject to any additional risk of serious or irreversible harm.

All other provisions of the Declaration of Helsinki must be adhered to, especially the need for appropriate ethical and scientific review.

*Clarification of paragraph 30*: The WMA hereby reaffirms its position that it is necessary during the study-planning process to identify posttrial access by study participants to prophylactic, diagnostic, and therapeutic procedures identified as beneficial in the study or access to other appropriate care. Posttrial access arrangements or other care must be described in the study protocol so the ethical review committee may consider such arrangements during its review.

2. It is the duty of the physician to promote and safeguard the health of the people. The physician's knowledge and conscience are dedicated to the fulfillment of this duty.
3. The Declaration of Geneva of the World Medical Association binds the physician with the words, "The health of my patient will be my first consideration," and the International Code of Medical Ethics declares that, "A physician shall act only in the patient's interest when providing medical care which might have the effect of weakening the physical and mental condition of the patient."
4. Medical progress is based on research which ultimately must rest in part on experimentation involving human subjects.
5. In medical research on human subjects, considerations related to the well-being of the human subject should take precedence over the interests of science and society.
6. The primary purpose of medical research involving human subjects is to improve prophylactic, diagnostic and therapeutic procedures and the understanding of the aetiology and pathogenesis of disease. Even the best proven prophylactic, diagnostic, and therapeutic methods must continuously be challenged through research for their effectiveness, efficiency, accessibility and quality.
7. In current medical practice and in medical research, most prophylactic, diagnostic and therapeutic procedures involve risks and burdens.
8. Medical research is subject to ethical standards that promote respect for all human beings and protect their health and rights. Some research populations are vulnerable and need special protection. The particular needs of the economically and medically disadvantaged must be recognized. Special attention is also required for those who cannot give or refuse consent for themselves, for those who may be subject to giving consent under duress, for those who will not benefit personally from the research and for those for whom the research is combined with care.
9. Research Investigators should be aware of the ethical, legal and regulatory requirements for research on human subjects in their own countries as well as applicable international requirements. No national ethical, legal or regulatory requirement should be allowed to reduce or eliminate any of the protections for human subjects set forth in this Declaration.

### B. Basic Principles for All Medical Research

10. It is the duty of the physician in medical research to protect the life, health, privacy, and dignity of the human subject.
11. Medical research involving human subjects must conform to generally accepted scientific principles, be based on a thorough knowledge of the scientific literature, other relevant sources of information, and on adequate laboratory and, where appropriate, animal experimentation.
12. Appropriate caution must be exercised in the conduct of research which may affect the environment, and the welfare of animals used for research must be respected.

13. The design and performance of each experimental procedure involving human subjects should be clearly formulated in an experimental protocol. This protocol should be submitted for consideration, comment, guidance, and where appropriate, approval to a specially appointed ethical review committee, which must be independent of the investigator, the sponsor or any other kind of undue influence. This independent committee should be in conformity with the laws and regulations of the country in which the research experiment is performed. The committee has the right to monitor ongoing trials. The researcher has the obligation to provide monitoring information to the committee, especially any serious adverse events. The researcher should also submit to the committee, for review, information regarding funding, sponsors, institutional affiliations, other potential conflicts of interest and incentives for subjects.
14. The research protocol should always contain a statement of the ethical considerations involved and should indicate that there is compliance with the principles enunciated in this Declaration.
15. Medical research involving human subjects should be conducted only by scientifically qualified persons and under the supervision of a clinically competent medical person. The responsibility for the human subject must always rest with a medically qualified person and never rest on the subject of the research, even though the subject has given consent.
16. Every medical research project involving human subjects should be preceded by careful assessment of predictable risk and burdens in comparison with foreseeable benefits to the subject or to others. This does not preclude the participation of healthy volunteers in medical research. The design of all studies should be publicly available.
17. Physicians should abstain from engaging in research projects involving human subjects unless they are confident that the risks involved have been adequately assessed and can be satisfactorily managed. Physicians should cease any investigation if the risks are found to outweigh the potential benefits or if there is conclusive proof of positive and beneficial results.
18. Medical research involving human subjects should only be conducted if the importance of the objective outweighs the inherent risks and burdens to the subject. This is especially important when the human subjects are healthy volunteers.
19. Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research.
20. The subjects must be volunteers and informed participants in the research project.
21. The right of research subjects to safeguard their integrity must always be respected. Every precaution should be taken to respect the privacy of the subject, the confidentiality of the patient's information and to minimize the impact of the study on the subject's physical and mental integrity and on the personality of the subject.
22. In any research on human beings, each potential subject must be adequately informed of the aims, methods, sources of funding, any possible conflicts of interest, institutional affiliations of the researcher, the anticipated benefits and potential risks of the study and the discomfort it may entail. The subject should

be informed of the right to abstain from participation in the study or to withdraw consent to participate at any time without reprisal. After ensuring that the subject has understood the information, the physician should then obtain the subject's freely-given informed consent, preferably in writing. If the consent cannot be obtained in writing, the non-written consent must be formally documented and witnessed.

23. When obtaining informed consent for the research project the physician should be particularly cautious if the subject is in a dependent relationship with the physician or may consent under duress. In that case the informed consent should be obtained by a well-informed physician who is not engaged in the investigation and who is completely independent of this relationship.
24. For a research subject who is legally incompetent, physically or mentally incapable of giving consent or is a legally incompetent minor, the investigator must obtain informed consent from the legally authorized representative in accordance with applicable law. These groups should not be included in research unless the research is necessary to promote the health of the population represented and this research cannot instead be performed on legally competent persons.
25. When a subject deemed legally incompetent, such as a minor child, is able to give assent to decisions about participation in research, the investigator must obtain that assent in addition to the consent of the legally authorized representative.
26. Research on individuals from whom it is not possible to obtain consent, including proxy or advance consent, should be done only if the physical/mental condition that prevents obtaining informed consent is a necessary characteristic of the research population. The specific reasons for involving research subjects with a condition that renders them unable to give informed consent should be stated in the experimental protocol for consideration and approval of the review committee. The protocol should state that consent to remain in the research should be obtained as soon as possible from the individuals or a legally authorized surrogate.
27. Both authors and publishers have ethical obligations. In publication of the results of research, the investigators are obliged to preserve the accuracy of the results. Negative as well as positive results should be published or otherwise publicly available. Sources of funding, institutional affiliations and any possible conflicts of interest should be declared in the publication. Reports of experimentation not in accordance with the principles laid down in this Declaration should not be accepted for publication.

### C. Additional Principles for Medical Research Combined with Medical Care

28. The physician may combine medical research with medical care, only to the extent that the research is justified by its potential prophylactic, diagnostic or therapeutic value. When medical research is combined with medical care, additional standards apply to protect the patients who are research subjects.
29. The benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic

methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic or therapeutic method exists.

30. At the conclusion of the study, every patient entered into the study should be assured of access to the best proven prophylactic, diagnostic and therapeutic methods identified by the study.
31. The physician should fully inform the patient which aspects of the care are related to the research. The refusal of a patient to participate in a study must never interfere with the patient-physician relationship.
32. In the treatment of a patient, where proven prophylactic, diagnostic and therapeutic methods do not exist or have been ineffective, the physician, with informed consent from the patient, must be free to use unproven or new prophylactic, diagnostic and therapeutic measures, if in the physician's judgement it offers hope of saving life, re-establishing health or alleviating suffering. Where possible, these measures should be made the object of research, designed to evaluate their safety and efficacy. In all cases, new information should be recorded and, where appropriate, published. The other relevant guidelines of this Declaration should be followed.

## 1 INTRODUCTION

The U.S. Food and Drug Administration (USFDA) is a scientific, regulatory, and public health agency that oversees what is estimated to be 25% of the consumer economy. The agency has jurisdiction over most food products, human and animal drugs, therapeutic biologic agents, medical devices, radiation-emitting products, cosmetics, and animal feed [1]. The FDA has a staff of approximately 10,000 employees including chemists, pharmacologists, toxicologists, physicians, microbiologists, veterinarians, pharmacists, lawyers, statisticians, project managers, and others. In this chapter, the role of the FDA and different scientific disciplines in the marketing approval of drug products in the United States are presented.

## 2 REGULATORY HISTORY

The FDA's mandate has evolved based on a number of legislative acts that have been introduced over the last 100 years. These are discussed below and outlined in Table 1. Regulatory functions were incorporated into the agency's mission in 1906 with passage of the Federal Food and Drugs Act. The 1906 law forbade interstate and foreign commerce in adulterated and misbranded foods and drugs. Drugs had to abide by standards of purity and quality set forth in the *U.S. Pharmacopeia* and the *National Formulary*, works prepared by committees of physicians and pharmacists, or meet individual standards chosen by their manufacturers and stated on their labels. The law prohibited the adulteration of foods by the removal of valuable constituents, the substitution of ingredients so as to reduce quality, the addition of deleterious ingredients, or the use of spoiled animal and vegetable products.

Another important milestone in the agency's history took place in 1938 with passage of the Federal Food, Drug, and Cosmetic (FDC) Act, which, for the first time, required new drugs to be shown safe before marketing. The FDC Act also extended the FDA's jurisdiction to cosmetics and therapeutic devices, authorized factory inspections, and added the remedy of court injunctions to the previous penalties of seizures and prosecutions.

In the late 1950s and early 1960s, a drug used in Europe for its sedative effects (thalidomide) was found to have caused birth defects in thousands of infants. The drug had been kept off the market in the United States. This event, as well as other factors, aroused public support for stronger drug regulation. In 1962, the

**TABLE 1 FDA Regulatory Landmarks**

| Year | Legislation | Features |
|---|---|---|
| 1906 | Food and Drugs Act | Defined FDA regulatory functions |
| 1938 | Food, Drug and Cosmetics Act | Requirement for safety data |
| 1962 | Kefauver–Harris Drug Amendments | Required demonstration of safety and effectiveness prior to marketing |
| 1992 | Subpart H | Accelerated approval of drugs for serious or life-threatening diseases |
| 1992 | Prescription Drug User Fee Act | Fees for product applications |
| 1997 | Food and Drug Modernization Act | Several reforms |

Kefauver–Harris Drug Amendments passed. In addition to more rigorous requirements for the demonstration of drug safety, this legislation required manufacturers to demonstrate to the FDA the effectiveness of their products prior to marketing.

In the 1980s and early 1990s, there was a growing recognition for the need to encourage the timely development and approval of drugs for serious or life-threatening illnesses such as HIV/AIDS (the human immunodeficiency virus/acquired immunodeficiency syndrome) and cancer. In 1992, subpart H was added to the new drug approval (NDA) regulations, allowing for accelerated approval (AA) of drugs for serious or life-threatening diseases where a drug demonstrates an advantage over available therapy or demonstrates its effects in a setting where no available therapy exists. Approval is based on a surrogate endpoint "reasonably likely to predict clinical benefit." The sponsor must study the drug further to demonstrate clinical benefit in subsequent or ongoing clinical trials [2, 3].

Also in 1992, the Prescription Drug User Fee Act (PDUFA) was enacted, requiring drug and biologic drug manufacturers to pay fees for product applications and supplements. The act also required the FDA to use these funds to increase the number and breadth of reviewer expertise for product applications. In 1997, the Food and Drug Modernization Act reauthorized PDUFA and mandated several reforms in agency practices [4]. Measures were introduced to accelerate review of devices, to regulate advertising of unapproved uses of approved products, and to regulate health claims for foods.

## 3 CLINICAL INVESTIGATIONS

In the United States, investigational drugs must be administered under an investigational new drug (IND) application submitted to the FDA. The regulations describe two parties involved in IND submission, the *sponsor*, who is responsible for reporting to the FDA, and the *investigator*, who performs the trial [5]. The sponsor may be a pharmaceutical company, an academic institution, or an individual. Sponsors are to select only investigators "qualified by training and experience as appropriate experts to investigate the drug."

When an IND is submitted to the FDA, a team of scientific reviewers evaluate the safety data from animals or other sources, evaluate the proposed study, and determine whether patients would be exposed to an unreasonable and significant risk. These issues are discussed individually in the sections below. All studies of nonapproved drugs must be done under an IND. For approved drugs, however, some studies require an IND and others are exempt from the IND requirement.

To determine that an IND is not needed, the following conditions should be met: The study (1) is not intended to support approval of a new indication or a significant change in the product labeling, (2) is not intended to support a significant change in advertising, (3) does not involve a route of administration or dosage level or use in a patient population or other factor that significantly increases the risks associated with the use of the drug product, (4) is conducted in compliance with institutional review board (IRB) and informed consent regulations, and (5) will not be used to promote unapproved indications [5].

The IND process spans the entire period of drug investigation (Fig. 1). It includes the initial IND application and later amendments to provide safety reports or

***FIGURE 1*** *Drug development timeline. The solid arrows indicate standard time points for meeting with drug developers. The dashed arrows indicate additional time points when the FDA sometimes meets with sponsors.*

additional protocols. The initial IND application usually consists of a phase I clinical protocol and data to support the safety of the proposal. The latter would include in vitro, animal, and/or human evidence describing drug toxicity and allowing prediction of a safe starting dose. Manufacturing data describing the composition, manufacture, and control of the drug substance and drug product is also included. After the FDA receives the initial IND, sponsors are required to wait 30 days prior to initiating the proposed study unless they request and receive a waiver of the 30-day review period from the FDA. A multidisciplinary team of FDA reviewers, including physicians, pharmacologist/toxicologists, chemists, statisticians, and clinical pharmacologists determine whether the study is safe to proceed. The FDA may put an IND "on hold" if the agency believes subjects would be exposed to unreasonable risk of injury or if there is insufficient information to assess the risks.

The FDA frequently meets with sponsors and investigators in pre-IND meetings to review proposed IND plans and to clarify IND requirements. Animal studies should use the same or a similar schedule of drug administration proposed for the phase I clinical study. The starting dose for investigational drugs used in human studies is usually based on a preclinical animal model, which may differ based on the type of product and the therapeutic area of development. FDA advice on the specific requirements for a given product should be sought from representatives of the responsible FDA review division.

A critical FDA role in drug development is to meet with sponsors to provide advice on the design and conduct of phase III (and sometimes phase II) clinical trials that will support marketing applications. The multidisciplinary FDA team attending these meetings includes physicians, statisticians, pharmacologists/toxicologists, clinical pharmacologists, and often external expert consultants and patient advocates. FDA chemists also meet with sponsors, often separately, to discuss manufacturing and quality control issues. Sponsors can submit protocols subsequent to these meetings and request a Special Protocol Assessment, which provides for a binding agreement on protocol design [6]. After the clinical trials have been conducted and trial results are available, sponsors again meet with the FDA in pre-NDA meetings to discuss whether a new drug application (NDA) may be warranted and, if so, to discuss details of an NDA submission.

After clinical trials have been completed and an NDA has been submitted, the FDA verifies data quality and judges whether trial results demonstrate that the drug is safe and effective for the proposed use. After approval, the FDA continues to evaluate drug safety and regulate drug marketing.

## 4 NDA REVIEW PROCESS

The package insert describes clinical trial results from data that have been reviewed and validated by FDA review teams. Regulations require that NDAs contain all relevant information about manufacturing, preclinical pharmacology and toxicology, human pharmacokinetics and bioavailability, clinical data, and statistical analyses. NDA applicants must submit financial disclosure information about the investigators. The FDA review of the NDA involves a team of chemists, pharmacologists/toxicologists, clinical pharmacologists, physicians, statisticians, microbiologists, site inspectors, and a project manager. The FDA reviewers evaluate the primary data, verify analyses, and where appropriate perform additional analyses. The FDA field inspectors verify that information on case report forms is supported by source data such as hospital charts and that biological drug concentrations are documented. Inspectors also inspect manufacturing facilities for suitability.

Based on the PDUFA, the FDA performs NDA reviews with either a 6-month or a 10-month goal. Applications representing a significant improvement compared to products that are currently available are assigned priority status and a 6-month review period, whereas standard applications have a 10-month review goal.

The FDA routinely seeks external advice on the design, analysis, and interpretation of clinical trials. These consultants are screened to exclude any potential conflicts of interest. Individual consultants advise the FDA during the design of clinical trials and during the NDA review. After an initial NDA review, the FDA presents selected NDAs to the appropriate advisory committee. This group is composed of medical and/or surgical specialists, statisticians, patient advocates, consumer representatives, and a nonvoting industry representative. At the public meetings of an advisory committee, the NDA applicant summarizes the study results, and the FDA presents its review of the findings. Members of the public may comment on the issues being discussed during the public speaker portion of the meeting. The committee finally votes on the specific questions submitted by the FDA. Although the discussion and the votes by the committee are taken into consideration, the FDA is not obligated to adhere to the advice provided.

## 5 PEDIATRIC INITIATIVES

There has been general recognition of the lack of adequate labeling of drug products for children. In order to encourage evaluation of new therapies in pediatric populations and to optimize submission of pediatric data to support labeling of commercially available drugs, the FDA has undertaken two initiatives, which are outlined in Table 2 and summarized as follows.

A voluntary program, commonly referred to as "pediatric exclusivity," was outlined in the Food and Drug Modernization Act of 1997. Under this program,

**TABLE 2 FDA Pediatric Initiatives**

| PREA | BPCA |
|---|---|
| Applies to drugs and biologics | Applies only to drugs |
| Studies mandatory | Studies voluntary |
| Required only for drug/indication under review | Studies on entire active moiety |
| Orphan indications exempted | Includes orphan drugs |

a commercial sponsor may receive a 6-month extension of existing marketing exclusivity by submitting data from pediatric clinical trials in support of an NDA. The general design of studies to be conducted and data to be submitted are outlined in a pediatric written request letter issued by the FDA to the sponsor. This program applies to drug products, including those with orphan designation. However, biological therapies such as monoclonal antibodies and vaccines are excluded. The Best Pharmaceuticals for Children Act (BPCA) subsequently provided some refinements to the program, including a framework for making summaries of medical and pharmacology reviews available to the public [7].

A mandatory program applying to indications where the disease in pediatric patients is similar to the adult disease, previously known as the "pediatric rule," was subsequently formally legislated in the Pediatric Research Equity Act (PREA) [8]. This mandatory requirement for sponsors to submit data from pediatric studies when an adult indication is granted applies to a specific drug and indication under review. In order to avoid the potential delay in drug development and in providing access to therapies for life-threatening diseases that can arise when the adult data support approval and pediatric studies are still ongoing, a deferral for submission of the pediatric data may be granted. Both drug and biologic products are subject to the PREA. However, products with orphan designation are excluded from this requirement.

## 6 ROLE OF STATISTICS IN REGULATORY SETTING

In 1962 the Kefauver–Harris amendment to the Food, Drug and Cosmetic Act (FD&C Act) led to the provision that the manufacturing companies need to provide substantial evidence of effectiveness and that the evidence show adequate and well-controlled investigations, including clinical investigations, by qualified scientific experts, that proves the drug will have the effect claimed by its labeling" [Section 505(d) FD&C Act of 1962 as amended]. Statistical methodology provides tools for objectively planning, conducting, and evaluating clinical trials. When evaluating the efficacy and safety of a drug from a regulatory perspective, two objectives have to be met: First, the claimed effect is true and, second, the effect is clinically meaningful with acceptable toxicity. The role of a statistical expert at the FDA is, using the data submitted by the applicant, to evaluate whether the claimed efficacy is in fact true. The statistical team works in conjunction with the medical team to evaluate whether the claimed effect is clinically meaningful and has an acceptable toxicity profile.

Before an application [an NDA or biologics license application (BLA)] for marketing approval is submitted to the FDA, product development would typically have

gone through several phases: preclinical phase and clinical phases I–III. Although statisticians are consulted at the design stage of each of these phases, the greatest impact of statistical advice is in planning and designing comparative, randomized, well-controlled studies (phase II or III registration studies). A randomized study mitigates potential selection and reporting biases and balances any known and unknown prognostic factors that may influence the outcome of the study. As detailed in Section 3, new product manufacturers can consult FDA staff by submitting the planned study protocol as an IND application. These protocols are reviewed by the FDA staff and comments are sent to the applicant. In reviewing these protocols including special protocol assessments (SPAs), the statisticians critique both the design and planned analysis of the study.

The protocol should clearly identify the study objective, the primary hypothesis (the benefit that is to be demonstrated), study population, and the primary outcome (or endpoint) that is being measured based on which efficacy claim is planned. The primary endpoint could be a binary outcome (e.g., proportion of patients cured of an infection), a continuous variable (e.g., lowering of cholesterol), or a time-to-event endpoint (e.g., overall survival, time to progression of disease). An endpoint may also be defined as a composite endpoint (e.g., myocardial infarction or death). In certain disease settings more than one endpoint may be of primary interest (e.g., the rate of acute rejection and survival for an organ transplant drug). The design and analysis of a trial depends on the endpoint that is being measured. In conducting and evaluating clinical studies, it is important to control false-positive claims or the so-called type I error rates ($\alpha$). The study also should have enough power or low type II error rates ($\beta$), so that a true effect, if it exists, can be detected with the number of patients enrolled in the study. Subjective endpoints, such as symptom measurements, are difficult to evaluate in open-label studies, and potential biases can be minimized in double-blinded studies [9].

In confirmatory, phase III comparative studies [10, 11], there are basically three types of hypotheses that are tested: (1) the new product is superior [new product compared to placebo; new product compared to an active control (standard treatment); the new product has a dose–response relationship]; (2) the new product is noninferior (the new product is not worse than the existing treatment—it may be better or it may have a similar effect); or (3) two products are bioequivalent [absence of any difference between the two products (e.g., generic drugs)]. Marketing applications with claims of superiority or noninferiority of new drugs are reviewed at the Center for Drug Evaluation and Research. For consideration of a noninferiority claim, the assumption that the patient population and the conditions of the current study with the new treatment are similar to the historical placebo-controlled trials with the existing treatment should be met, the effect of size of the existing treatment must be well established, and that a certain prespecified percentage of the historical control effect size is maintained. Because of these assumptions, in general, noninferiority claims are difficult to establish and require large studies. In hypothesis 3, bioequivalence studies of generic products are generally reviewed by the Office of Generic Drugs at the FDA.

The sample size required to conduct a clinical trial that will ensure that the study is informative to test the primary hypothesis depends on the primary endpoint of interest, the smallest difference in treatment efficacy, which is important enough to detect, the probability of type I error (significance level), the probability of type II

error (1, power of the test), the number of interim analyses that are planned, the number of endpoints, and the comparisons that are being evaluated. If interim analyses or multiple comparisons are planned, then the type I error rate allocated for testing the final analysis has to be adjusted so that the overall familywise type I error rate is maintained at the specified level [10]. Sometimes, meta-analysis, a technique combining results from different studies, is used to provide benchmarks for new agents and new indications and in the design stage of clinical trials.

The statistical analysis plan should be prespecified. The statistical analysis plan should include definitions of the primary and secondary endpoints, and the hypotheses and the analysis plan for each of the endpoints. Comparative analyses based on secondary endpoints are considered exploratory and hypothesis generating if the familywise type I error rate is not maintained at the prespecified level. A post hoc analysis and claim based on a subgroup of patients, when the efficacy could not be demonstrated in the overall study population, is considered exploratory and hypothesis generating, and are generally not considered suitable as a basis for drug approval.

During an ongoing clinical trial, any changes in the definition of endpoint, changes in the type of hypothesis being tested, change in study population, additional interim analyses, increasing sample size, and other study modifications are problematic if the modifications or adaptations are not based on established statistical methods. Such modifications could compromise on the integrity of the study and introduce bias in the interpretation of the results, particularly in an open-label study. Too many modifications and adaptations of the study design and conduct are considered as exploratory. In general drug product approval is based on statistically persuasive results that are clinically meaningful with adequate efficacy and safety.

## 7 ROLE OF CHEMISTRY, MANUFACTURING, AND CONTROLS (CMC) INFORMATION IN REGULATORY SETTING

As per regulations [12], the sponsor must submit CMC information that will describe the general method of preparation of the drug substance, physical, chemical, and biological characteristics, drug product formulation, manufacturing process, and controls to provide assurance of the identity, strength, quality, purity, and potency of the investigational drug. The CMC information that is expected in an initial IND (phase I) is more to assure patient safety and less on product and process controls. However, for phase II and phase III studies, as more manufacturing experience is attained with the manufacturing process and the final formulation is chosen, more exhaustive details regarding process and product controls should be provided. The amount of CMC information required is also dependent on the type of molecule to be tested (e.g., synthetic, semisynthetic, naturally derived, biotechnological) and whether there is any previous clinical experience with the study drug.

The amount of CMC information that will be required in an IND will also be dependent on the marketing status of the drug product. For a drug that is already marketed in the United States, the investigator should provide the current approved labeling and/or package insert of the drug. If a drug is not marketed in the United States, but studied under a cross-referenced IND, the sponsor should provide a letter of authorization (LOA) from the sponsor of the cross-referenced IND to allow the

agency to access to the referenced IND. The LOA should clearly specify the name, strength, and dosage form of the drug. If a drug is not marketed in the United States or it is not referenced to an IND, the sponsor should provide CMC information on the study drug appropriate to the phase of the study. If the drug is intended to be administered for intravenous administration after dilution, compatibility data with different diluents and in-use stability data for the duration of administration should be submitted. Please refer to the following guidance documents regarding the CMC information that needs to be submitted to support the proposed clinical study in the IND [13, 14].

If a drug is not marketed in the United States, but approved and marketed in a foreign market, or it is a legally marketed dietary supplement, the sponsor should provide full CMC information [13, 14]. For a limited phase I study, this requirement may be fulfilled by providing the following information: components and composition of the drug product, name of manufacturer/supplier of the drug product, and the labeling and/or package insert.

The sponsor should also provide a certificate of analysis for the lot that is intended to be used in the proposed clinical trial. Additional product-specific information may be required for the drugs approved and marketed outside the United States or for a legally marketed dietary supplement in the United States. When a sponsor is faced with a situation that is unique and not covered by the above guidance(s) [13, 14], the FDA recommends that the sponsor obtain clarification from the review division with regard to the CMC information necessary to support the proposed clinical study. For a botanical drug, the CMC information that needs to be submitted may be different from that of conventional small-molecule drugs [15].

For all drugs, the sponsor should provide a statement in the CMC section (as well as under dosage and administration section of the clinical protocol), as to the labeled dosage form and the strength of the drug product and how the drug will be administered. If the sponsor intends to change from the labeled dosage form, strength, or route of administration, the sponsor should provide relevant information such as release and stability data to support the change as well as to assure that the change will not adversely affect the identity, strength, quality, purity, and potency of the investigational drug. For all investigational drugs, the following labeling and environmental assessment information should be provided; the label for the immediate packaging of the drug product should be provided that includes the following cautionary statement: "Caution: New Drug—Limited by Federal (or United States) law to investigational use" [16].

A statement requesting a categorical exclusion from environmental assessment under provisions provided for in 21 CFR § 31(e); Part 25, Environmental Impact Considerations; Subpart C, Categorical Exclusions; Section 31, Human Drugs and Biologics, Paragraph (e)—Action on an IND [17].

If a device is used in conjunction with the study drug (e.g., a nebulizer for an inhalation drug or a pump for continuous infusion for home use), information on the manufacturer and model of the device to be employed and a general description of relevant conditions of use (e.g., carrier gas, flow rate, temperature) should be provided. A statement as to whether the device is FDA approved or not approved should also be included. When appropriate, submit adequate information regarding safety instructions for use of equipment and disposal of unused portion of the drug.

## 8 ROLE OF CLINICAL PHARMACOLOGY IN REGULATORY SETTING

The purpose of clinical pharmacology and biopharmaceutics data is to support the determination that the drug to be marketed is safe and effective for use in the indicated patient population. The clinical pharmacology data in conjunction with the safety and effectiveness data from the registration clinical trial(s) can be used to understand the relationships between drug dose or concentration and effects, namely patient outcome and toxicity (exposure–response relationships, ER). These relationships allow for better choices regarding optimizing the dose for the patient population, adjusting doses in special clinical situations, and providing information in the product labeling. Some of these studies provide direct support for the assessment of ER, such as pharmacokinetic information derived from clinical studies (see Fig. 1). On the other hand, some clinical pharmacology and biopharmaceutic data provide indirectly to understanding the behavior of the drug in the patient. For instance, in vitro cytochrome P-450 (CYP 450) screening often indicates whether the drug is metabolized by or modulates any of these enzymes. These in vitro data may suggest whether or not in vivo drug–drug interactions might occur between the drug being developed and other medications that may be commonly administered to a particular patient population that may lead to toxicity or reduced effectiveness.

The summation of these studies should provide appropriate information on drug behavior and its safe and effective use in the product labeling. With that goal in mind, the clinical pharmacology and biopharmaceutics studies can be used collectively to address some basic questions about the drug and how to use it appropriately. With respect to labeling the drug, the main questions are: Is this dose the optimal dose for this patient population? Are any dose or dose regimen adjustments needed for patients with specific clinical characteristics? The answer to these questions are quite complex. Many different chemical, pharmacological, and clinical aspects of the drug contribute to the answers. In the Appendix, many questions about the clinical pharmacology of the drug are posed, and these specific answers, once determined, contribute to the overall issues regarding the optimal dose, dose adjustments, and the safe labeling of the drug.

To address many of these specific issues, the FDA has publicly posted or is planning to post Guidances for Industry that describe the current thinking of the FDA on a specific topic [18]. Each of these is intended to be a general set of guidelines to deal with a specific issue; they may not address every situation, but they should be the starting point for dealing with the issue of interest. Essentially, these are located on the FDA website under the Biopharmaceutics, Chemistry, Clinical, and Clinical Pharmacology headings [18]. The Biopharmaceutics and Chemistry Guidances address issues that affect the drug formulation and may have an impact on how the drug product behaves after administration to the patient (i.e., how much drug may be absorbed). For instance, changing the ingredients of a tablet may alter how quickly the tablet dissolves after administration to the patient, which may have an impact on the absorption of the drug and therefore its effect(s). The Clinical Pharmacology Guidances describe what happens to the drug, and hence its impact on the patient once it is administered to the patient. For instance, renal impairment may cause the exposure of drug to increase because drug elimination is reduced. This in turn may increase the rate of drug toxicity and may necessitate a dose adjustment in these patients.

### 8.1 Biopharmaceutics Guidances

The Bioanalytical Method Validation Guidance [19] is designed to verify that the analytic method used to measure drug concentration is accurate and reliable for the purpose it is intended. The Food Effect Guidance [20] describes the general issues to be considered when assessing the effect of food on a per oral formulation. It addresses the biopharmaceutics issue of how food taken with a medication can alter the dissolution and absorption of a given product. The outcome of this study is often used to determine how the drug should be administered in future trials and, eventually, the intended patient population. During drug development, it is common for a drug developer to alter the drug formulation. These changes may impact the pharmacokinetics and pharmacodynamics of the drug in the patient, and these formulation changes raise questions about how to "bridge" (compare) data from different studies developed with different formulations. The Dissolution Guidance [21] and the Bioavailability and Bioequivalence Guidance [22] are closely related in purpose. Both methodologies are intended to assess the effect of changes in the product formulation on the pharmacokinetics and, by extension, the pharmacodynamics of a drug. The dissolution guidance describes how an in vitro method can be developed using well-defined apparati and criteria. The purpose is to develop a discriminatory in vitro method to assess alterations in the formulation of a per oral drug product (similar approaches can be used to develop an in vitro drug release methodology for a liposome drug product). For instance, changing an ingredient may have an impact on the rate that the tablet dissolves in the gastrointestinal milieu. One could expect that this could alter the extent to which a drug is absorbed and the timing of this event. This could result in undesired effects in the patient (reduced effectiveness or increased toxicity). However, significant changes in dissolution do not necessarily indicate clinically significant changes in the behavior of the drug, so monitoring changes in dissolution is the first step in assessing the impact of a formulation change. Such an in vitro observation is likely to be further assessed by observing the effect of the new formulation in vivo. The Bioavailability/Bioequivalence Guidance [22] describes in general terms the elements of a study for comparing the pharmacokinetics and pharmacodynamics of a preexisting drug formulation with a newly developed one. Studies of dissolution and pharmacokinetics conducted early in drug development can lead to the development of in vitro–in vivo correlations [23] in which a clinically meaningful dissolution method can be used to predict in vivo performance of new formulations. These IVIVC relationships are often used in the development of modified-release drug products.

With regard to clinical pharmacology studies, the characterization of the drug often begins with in vitro studies. Protein binding, although not the subject of a specific guidance, is usually assessed with in vitro incubations for each new drug. (There are examples of ex vivo protein binding determinations as well.) Current scientific thinking is that only free or unbound drug can mediate drug action. Therefore, highly protein-bound drugs (≥90%) have their pharmacological effects mediated by only a small fraction of drug. Furthermore, small changes in protein binding for these drugs might be expected to mediate a substantial effect. Therefore, the extent of protein binding to human serum proteins (e.g., albumin, α-acidic glycoprotein) is commonly performed.

The Drug Metabolism Guidance describes both in vitro and in vivo studies [24, 25]. The in vitro studies describe cytochrome P-450 (CYP 450) screening. The CYP 450 superfamily of enzymes accounts for the majority of drug metabolizing capability in humans. In vitro screening often identifies the main isozyme(s) responsible for the metabolism of a particular drug and the extent of its contribution. New drugs can also be screened for their ability to either inhibit CYP 450 isozyme(s) activity or induce their activities and expression. The end result may be reduced drug clearance or increased drug clearance, respectively, which may affect effectiveness and/or safety. These in vitro findings can then be used as the basis for deciding on the need to conduct in vivo drug–drug interaction studies. It is noteworthy that these in vitro studies do not account for the activity of all metabolizing enzymes, and the metabolism and potential drug–drug interactions on non-CYP 450 metabolized drugs are often difficult to assess. One non-CYP 450 enzyme system that has been studied further is the P-glycoprotein (PGP) transporter system. A newly published draft Guidance on Drug Metabolism describes both in vitro and in vivo studies to assess the impact of new drugs on PGP [26].

Related to the in vitro metabolism studies in purpose are the in vivo "mass balance" studies. These studies are not the subject of a specific guidance but are referred to in some agency publications. The purposes of these types of studies are generally twofold. The first is to determine whether a novel metabolite is generated in humans that has not been previously characterized (at least in part) in preclinical studies. The second purpose is to assess the route of excretion/elimination from the patient. This latter purpose is of importance because it can indicate that patients with organ dysfunction may have difficulty eliminating the drug, which in turn can lead to excessive drug exposure and toxicity. The results of these studies are used to determine whether pharmacokinetic studies in patients with either renal and/or hepatic impairment should be conducted. One common misinterpretation regarding mass balance studies is that the administration of radiolabeled drug is required. This, in fact, is untrue. Any appropriate methodology may be used to assess mass balance. However, use of radiolabeled drug is often employed because of the considerable sensitivity imparted by the methodology.

## 8.2 Clinical Pharmacology Guidances

The basic elements of the pharmacokinetic characterization (clearance, CL, volume of distribution, $V_d$, and elimination half-life, $t_{1/2}$) are characterized in the Format and Content of Human Pharmacokinetics and Bioavailability Section of an Application Guidance [27]. Essentially, the kinetics should be determined to better understand the behavior of the drug. Typically, single- and multiple-dose pharmacokinetics are assessed, usually in early studies in volunteers or patients. Dose proportionality is often assessed with the data generated from these studies. The exposure–response guidance describes the different measures that can be used to evaluate the relationships between drug amount and its effectiveness and toxicity(ies) [28]. These relationships are of great importance because they are the basis for understanding the behavior of the drug and for making rational decisions about choosing the optimum dose or altering the dose when necessary. The Population Pharmacokinetic Guidance [29] describes alternative approaches to assessing the pharmacokinetics of a drug. In some drug development circumstances, the execution of a dedicated phar-

macokinetic study with dense sampling may not be feasible. In these cases, an alternative approach can be employed to collect pharmacokinetic data in a more limited fashion. These data are often combined with previously collected data, and the effects of different factors (covariates) such as disease, patient demographics, and patient characteristics can be assessed, often by using sparse sampling.

The guidances on the effect of renal [30] or hepatic impairment [31] on the pharmacokinetics of a drug also describe important studies. Most drugs are renally excreted or metabolized (predominantly by the liver) prior to elimination or sometimes both. As drug exposure is a function of both the administered dose, and the rate of elimination, renal or hepatic impairment can lead to significant reductions in drug elimination, which in turn produce excessive drug exposures (e.g., higher than anticipated plasma concentrations). Sometimes these elevated concentrations lead to toxicities. Ideally, by understanding the pharmacokinetics (PK) and the pharmacodynamics (PD) of the drug in both the general patient population and in those patients with organ dysfunction, rational dose modifications can be made.

The agency has also published a guidance on the evaluation of QT prolongation [32], which describes how to assess the potential of a drug to adversely affect cardiac conduction.

The agency has also been developing new guidances that deal with issues of drug PK in pregnant women [33] or lactating women [34], as well as in pediatric patients [35].

Recently, the FDA also implemented the EOP1/2a Guidance [36]. The purpose of this guidance is to encourage drug developers to employ all of the available preclinical biomarker, toxicity, and pharmacokinetic and chemistry information along with existing clinical data on effectiveness, biomarkers, and pharmacokinetics in a comprehensive model and to subsequently simulate the outcomes of different drug development trials with different regimens, combinations, and dosages to help choose the most effective trial design for the pivotal trial. In a similar vein, the agency has also issued the Guidance for Industry on Pharmacogenomic Data Submission [37] in a effort to stimulate the development of testing platforms and analysis and utilization of pharmacogenomic data in clinical trials in order to develop better, targeted therapies.

### 8.3 Timing of Studies

With respect to when these studies should be conducted, there is no regulatory requirement. It is up to the drug development sponsor to decide on when and how to allocate resources to these studies. However, there is some sense to the order and timing of these studies. For instance, there may not be too much value in conducting a mass balance study in parallel with the phase III safety and effectiveness trial, if the active metabolites have been identified and organ dysfunction studies have been conducted (or planned). Figure 2 depicts one possible scheme of clinical pharmacology and biopharmaceutics study conduct. According to this scheme, development begins with preclinical studies. The extent of protein binding is determined, and the compound is screened in vitro to evaluate it as a substrate for, or inhibitor and/or inducer of, CYP 450 enzymes. The compound is also screened as a substrate or inhibitor of P-glycoprotein. Additionally, biomarkers may be selected as potential indicators of activity based on animal and in vitro models. Other preclinical studies

***FIGURE 2*** *One possible clinical pharmacology drug development scenario is depicted. The FDA does not regulate the timing of studies in drug development.*

generate information regarding the toxicity of the compound, including the potential to alter cardiac function (e.g., hERG assay). The analytical method chosen to measure in vivo drug concentrations is often adapted from preclinical to clinical use and validated.

With the first-in-man studies, and ideally throughout the completion of the phase III trial(s), the pharmacokinetics are assessed. Single-dose and multiple-dose pharmacokinetics are usually determined in the dose escalation phase I study(ies), and dose proportionality and time-dependent changes in the pharmacokinetics can be assessed with this data. In some cases, population PK/PD modeling is started with the development of the base model using this data. Collection of samples for pharmacokinetic analyses from phase II may be correlated with markers of effectiveness and toxicity. Drug development according to this scheme would lend itself to an EOP2a analysis, and subsequent simulation of possible phase III trial designs, which may be very helpful in choosing the most efficient regimens, doses, combinations, and/or patient populations. In the late phase I early phase II period, it may be advisable to assess the effect of food on the pharmacokinetics of orally administered drugs in order to decide how to administer the drug in the pivotal trial and the intended patient population. It may also be helpful to consider the effect of two drugs that may be co-administered together. For instance, in oncology, drugs developed for glioblastoma multiforme are often administered with antiepileptic medications, such as phenytoin. The latter drug induces CYP 450 3A4 expression and often reduces the plasma concentrations of the new drug to levels that are too low to be effective. In these cases, the new drug is often developed with concomitant use in all later studies and is labeled for use specifically in combination with each other.

Often in this time frame, thorough QTc studies are performed to assess the potential for the drug to prolong the QT interval, and possibly generate torsades de pointes. Mass balance studies are often conducted some time between the first-in-man studies and phase II. Drug–drug interaction studies and organ dysfunction studies are often conducted in parallel to the phase III, when the decision has been made to pursue the drug marketing. Bioequivalence studies are conducted at various

points during development, from phase I to postdrug approval, depending on the development of the drug formulation and oral preparations with new strengths.

## 9 DRUG REGULATION IN GLOBAL ENVIRONMENT

Drug development has become a global effort with clinical trials in several disease areas often involving a multitude of centers across the globe. Even when some individual clinical trials are conducted in one country or region, a package submitted for approval purposes often includes trials conducted in a number of regions around the world. Even when individual trials are conducted in one region, commercial sponsors usually have a global strategy aimed at marketing approval in a number of countries and regions. While international activities take place in virtually every component of the FDA, the Office of International Programs (OIP) is the focal point for the agency's international activities. It provides leadership for FDA's international activities by guiding and supporting agency programs and by developing strategic relationships with other U.S. and foreign governmental agencies and international organizations. While the FDA takes a proactive role in these activities, it is also worthwhile to discuss not only the role of the FDA but to also describe the roles of other regulatory agencies around the world. The following is a brief introduction to drug regulation in Canada, Europe, Australia, and Japan.

The Therapeutic Products Directorate (TPD) is the Canadian federal authority that regulates pharmaceutical drugs and medical devices for human use and is housed within Health Canada (Ministry of Health) [38]. Prior to being given market authorization, a manufacturer must present substantive scientific evidence of a product's safety, efficacy, and quality as required by the Food and Drugs Act. The Biologics and Genetic Therapies Directorate (BGTD) has regulatory oversight for biologics, radiopharmaceuticals, genetic therapies, and the transplantation of tissues, cells, and organs.

With headquarters in London, the European Medicines Agency (EMEA) is a decentralized body of the European Union (EU) that coordinates a network of 42 national agencies and has undergone significant changes concurrent with the enlargement of the European Union [39, 40]. Its main responsibility is the protection and promotion of public and animal health through the evaluation and supervision of medicines for human and veterinary use. The EMEA began its activities in 1995, when the European system for authorizing medicinal products was introduced, providing for a centralized and a mutual recognition procedure. The EMEA has a role in both, but is primarily involved in, the centralized procedure. Where the centralized procedure is used, companies submit one single marketing authorization application to the EMEA. A single evaluation is carried out through the Committee for Medicinal Products for Human Use (CHMP) or Committee for Medicinal Products for Veterinary Use (CVMP). If the relevant committee concludes that safety and efficacy is proven, it adopts a positive opinion. This is sent to the Commission to be transformed into a single marketing authorization for the whole European Union. Since 2005, applications for marketing authorization within the European Union for diabetes, AIDS, cancer, neurodegenerative disorders, and for products with orphan designation have required submission exclusively through the centralized procedure [40].

In Australia, the Therapeutics Goods Administration (TGA) has authority in the regulation of prescription and nonprescription medicines, medical devices, and gene technology products. The TGA guidelines are aligned with those of the European Union and the International Conference on Harmonisation (ICH) of drug regulatory activities. Further information on drug regulation in Australia can be found on the official webpage [41].

In Japan, regulatory activities have been consolidated into the Pharmaceuticals and Medical Devices Agency (PMDA) since 2004. The PMDA is authorized by the Ministry of Health, Labor and Welfare (MHLW) and includes a staff of approximately 250 personnel including reviewers. The PMDA is comprised of four offices: Office of Relief Funds, Office of Review, Office of Safety, and Office of Research and Development Promotion. Further information on drug regulation in Japan can be found on the official PMDA webpage [42].

In China, regulation of foods, drugs, cosmetics, and traditional Chinese medicinal preparations is the purview of the State Food and Drug Administration (SFDA). Drugs are regulated by the Center for Drug Evaluation (CDE). Further information on drug regulation in China can be found on the official SFDA webpage [43].

## APPENDIX CLINICAL PHARMACOLOGY DRUG DEVELOPMENT QUESTIONS

### Exposure–Response Questions

1. What are the concentration/dose–response relationships? (ER, population PK)
   What are the effectiveness endpoints? In vivo
   - Biomarkers?
   - Clinical outcomes?

   What are the safety endpoints? In vivo
2. What are the factors that affect the concentration–response relationships? (ER)
   Do pharmacogenomics affect the ER? In vitro, In vivo (VGDS)
   What is the extent of protein binding? Does it impact ER? In vitro
   Are there active metabolites that contribute to ER? In vitro (drug metabolism/drug interaction)
   What are the characteristics of metabolism and elimination that affect the ER?
   Is the drug eliminated by metabolism, renal excretion, or both (some other route?)? in vitro, in vivo (drug metabolism/drug interaction)
   Is the drug a CYP 450 isozyme(s) substrate, inhibitor, induce? In vitro
   Are in vivo drug–drug interaction studies needed to assess impact? In vivo
   Are labeling instructions necessary?
   Is the drug a P-glycoprotein substrate or inhibitor? In vitro (drug metabolism/drug interaction)
   Are in vivo drug–drug interaction studies needed to assess impact? In vivo
   Are labeling instructions necessary?
   Are there metabolic polymorphisms that affect metabolism/elimination? In vitro, In vivo (drug metabolism/drug interaction)

Are in vivo drug–drug interaction studies needed to assess impact?
Are labeling instructions necessary?
Are in vivo studies in patients with hepatic impairment needed to assess the need for dose adjustments? In vivo (hepatic impairment)
Are in vivo studies in patients with renal impairment needed to assess the need for dose adjustments? In vivo (renal impairment)
Does age have any effect? In vivo (21 CFR 314)
Does race have any effect? In vivo (21 CFR 314)
Does gender have any effect? In vivo (21 CFR 314)
Are the ER the same in pediatric populations? In vivo (Pediatric PK)
Are specific dosing instructions/regimens required?

3. What biopharmaceutics issues affect ER of the drug?
   Can the active moieties of the drug be accurately measured? In vitro, In vivo (Bioanalytical method validation)
   What is the extent of absorption? In vitro, in vivo (21 CFR 320, BA/BE, BCS Classification)
   Are there different formulations of the drug that affect the ER? In vitro, In vivo (BA/BE, dissolution, IVIVC, SUPAC, IR, MR)
   Are there different oral formulations that absorbed differently?
   Is there a modified intravenous formulation that affect ER? In vitro, in vivo (Liposome drug products) e.g., liposomal drug, antibody-conjugated drug, etc?
   How does food affect absorption of an oral formulation? In vivo (Food effect)

## 1 INTRODUCTION

Clinical development faces two major challenges: public trust and productivity. Costs in drug development have increased substantially over the past decades [1]. Notwithstanding this development, the number of new drugs that are implemented in clinical practice has not increased but rather decreased in recent years [2]. At the same time, recent opinion polls [3] show that the public trust in pharmaceutical companies has fallen sharply and is now almost at a level comparable to that of the oil and tobacco industries. While some may argue that these challenges of public trust and productivity are difficult to align, we consider both to be essential and indeed mutually dependent. If public trust in clinical trials decreases, recruitment of patients for clinical trials will be more difficult, which in turn will result in even poorer productivity.

The ambition of improving public trust, especially in view of the tragic incident at Northwick Park Hospital in March 2006, has much to do with heightening ethical standards. The dual objective of this chapter is therefore to clarify the nature of the ethical challenges that lie ahead and to specify the design features that can increase productivity in individual clinical trials under ethically acceptable standards. Our question could be formulated as follows: Given that clinical trials should meet stringent requirements, how can productivity be maximized? In order to formulate an answer to this question, we will first have to specify the ethical requirements. Once these have been formulated, we will provide a method of analyzing trial efficiency and will give examples of how productivity can be increased. In doing so, we will consider specifically how to optimize the information per patient, approach sample size determination from a business perspective, and choose between adaptive design options.

This reflection is inspired by decision analysis (DA), which is a method that aims at optimizing different kinds of decisions, often by analyzing trade-offs. The essential assumption of DA is that different objectives can be valued on a common scale. For example, if one treatment offers better health benefits while the other provides better safety, it is possible to compare the two and choose the treatment that maximizes the net utility for the patient. Furthermore, even if the respective health benefits and safety features of these treatments are uncertain, DA offers the possibility of comparing the expected utility of the two treatment options. In this study, the first DA will be patient-centered, meaning that the net utility of the *patient* will be focused. After and secondarily to that, the interests of science and the sponsor of the trial will be considered, and a commercial optimization of clinical trials will be outlined. This priority is, in our minds, the only one that is ethically acceptable.

### 1.1 Introducing Public Trust

The study will therefore begin by a broad review of the ethical issues facing clinical development and more specifically randomized clinical trials (RCTs). In doing so, we formulate three minimal ethical requirements that should be met before patients can be enrolled in RCTs: genuine consent, patient benefit optimisation (PBO), and nonexploitation. These requirements are addressed principally to physicians who ultimately are responsible for their patients' health and for the enrollment of their

patients in any RCT. Our requirements do not cover properly scientific or regulatory concerns, and it is taken for granted that any clinical trial must also be examined and approved by an ethical committee or an investigational review board (IRB). In addition, we take for granted that regulatory approval is needed to administer new pharmaceuticals outside clinical trials. A more detailed list of ethical requirements covering such scientific and regulatory issues has been formulated by Emanuel et al. [4].

The core issue being treated here is therefore the physician/patient relationship and how it is affected by the collaboration of the former in clinical development. We argue that this collaboration does call into question the physician's fiduciary commitment to the well-being of his patient, as he or she must concurrently serve the interests of science. Such collaboration, which constitutes a threat to patient trust, can only be ethically justified through the consent process in which the patient acquiesces to participate in an RCT. The patient's informed consent in this matter should therefore not only be a formal but genuine and be based on relevant and appropriate information allowing the patient to formulate a well-reasoned judgment about such participation.

While this genuine consent is a necessary condition, it is not a sufficient prerequisite for trial participation. There are instances when the patient might accept to take part in a trial but when such participation would nonetheless be unethical. Such situations might arise if the patient is not sufficiently informed or free to consent or decline trial participation or when the trial design itself is morally skewed. That is why the physician, who is ultimately responsible for the patient's medical well-being, must be certain that he or she can, in good conscience, propose an RCT to his or her patient. Traditionally, this ethical peace of mind has been sought in the state of equipoise, understood as a state of "genuine uncertainty" on the part of the physician as to the merits of the respective arms of the trials. We argue, in a Bayesian perspective, that such genuine uncertainty in reality never exists. The physician has always a hunch or can second guess, on the basis of medical competence and experience, which arm in the RCT will receive the best treatment. An appeal to equipoise alone will therefore not do. We believe that the only way to ethically justify physician collaboration and patient participation in a RCT is the requirement of patient benefit optimization, that is, the judgment that the patient will benefit more from inclusion in the trial than from exclusion [5].

Besides genuine consent and patient benefit optimization, there is a third ethical requirement that we believe is essential: the principle of nonexploitation. It stipulates that no coercion should be used in the recruitment of patients. In other words, a patient or volunteer must be provided with sufficient freedom to willingly accept or decline an invitation to enroll in a RCT. The research subject might not, for instance, feel free to decline an offer to participate in a trial if this would result in, for example, inferior treatment. Such a situation can arise when research is carried out in developing countries or if patients are required to participate in a clinical study in order to qualify for medical coverage.

### 1.2 Introducing Productivity

Within the framework of these ethical requirements, the sponsor must design the most efficient trial. What does efficiency mean, however? Just as different

therapeutic treatments have medical pros and cons, trial designs have also relative benefits and drawbacks. Thus, DA is useful, not only in evaluating the ethical issues involved but even more so in the analysis of efficiency. In Section 3.2 we propose a detailed 10-step DA approach to clinical development. In this introduction, we limit ourselves to outlining the four most important steps, which are (1) modeling background information, (2) specifying trial objectives and utilities, (3) identifying design options, and (4) optimizing the decision of the three previous steps.

Experimentation is driven by the need to know more about the medical effects and safety features of a certain drug. It is therefore important to evaluate the information that is already available and to quantify the level of uncertainty. Existing information about the drug's characteristics can usually be compiled from a number of sources. Previous clinical trial data are often limited, especially in early clinical development. To fill in the information gap, investigators can refer to preclinical data, literature on the disease and related drugs, and expert input. In a DA approach, a quantitative model must first be constructed based on already existing information and a set of assumptions. These assumptions are necessarily subjective and should therefore be challenged during the analysis process. Then the objective of the trial must be formulated from a wide enough context in order to avoid suboptimization. The overall objective is then converted into quantitative preferences, which can be called utilities. The utility is thus a function of the outcome of the trial and reflects both the value of information as well as the cost of experimentation. In Section 3, we will take the commercial net present value (NPV) as an approximation of the utility of the trial sponsor. Third, DA can help to identify the designs and to tailor them in such a way that they are compatible with the objectives of the experiment. Still today, many trials are given standard designs, without taking into account its specific objectives. We therefore argue that standard procedure, at the outset of any trial, should be to generate, through project team brainstorming, a number of designs by considering common options such as cross-over, adaptive, and enrichment designs. Finally, the fourth step consists in predicting the trial results for the different designs. These predictions are made from the model and are typically carried out by computer simulations. When this is done, the predicted trial outcomes can be combined with the utility function. An expected utility can then be calculated and the optimal trial be designed in view of maximizing this value. By questioning the underlying assumptions and making tentative modifications of them, the robustness of this result can be verified.

The DA approach will thus be the dominating framework when discussing different aspects of study design. We will therefore discuss how much information should be obtained from each patient in view of optimizing the design (Section 3.3). Multiple measurements and multiple treatments (cross-over study) for each individual will yield more information but might also cost more and cause methodological problems. It is therefore important to analyze the optimal amount of information to purchase, that is, the optimal sample size when information value is compared with the cost of the experiment (Section 3.4). Finally, we will consider some sequential and adaptive designs where the trial design decisions depend on accumulating information (Section 3.5).

A number of recent trends in clinical study methodology and technology are supporting the DA approach to trial optimization. Model-based drug development,

and especially pharmacokinetic/pharmacodynamic (PK/PD) modeling, are being used more and more by the industry and are being promoted by regulators. The Food and Drug Administration (FDA) has stated that a drug may, in some instances, be approved on the basis of only one single confirmatory trial when supported by modeling results. The increase in computer speed has opened the way for nonlinear mixed-effect models as well as for Bayesian methods, where a probability model is updated with accumulating data. New design options are identified, and there has been an increasing interest in adaptive designs during the last decade. Web-based data capture has greatly facilitated the practical implementation of sequential and adaptive designs. The interest in decision-analytic approaches is on the upswing, and methodological work is being done in related areas, ranging from the psychology of decision making to the integration of commercial values in sample size determination.

## 2 CHALLENGE OF PUBLIC TRUST

From the point of view of medical ethics, clinical trials are problematic because they challenge the generally held view that the principal responsibility of physicians is to further the well-being of the individual patient. This responsibility is the cornerstone of the physician–patient relationship. As Ruth Purtilo argues [6], the professional's priority to further the welfare of the patient:

> is interpreted to have the stringency of a special moral obligation on the part of the professional to seek a patient's well-being, guided by that person's health-related concerns and needs. Any other worthy goal, such as furthering knowledge about disease and its cure, or earning a just wage, or maintaining the efficiency or financial solvency of the institution, is not an appropriate beacon to guide the professional in this relationship.

This hallow responsibility is enshrined in most codes of ethics regulating medical conduct and has enjoyed almost universal recognition. In the Oath of Hippocrates (Greece, 4th century B.C.E.), the physician swears to apply his art "for the benefit of the sick according to my ability and judgment" adding that he will keep the sick "from harm and injustice." In the Indian tradition, the Oath of Initiation (Caraka Samhita) from the first century C.E. puts it another way: "Day and night, however you may be engaged, you shall endeavour for the relief of patients with all your heart and soul." Similar enjoinders can be found in the Advice to a Physician (Persian tradition 10th century C.E.) and in the 17 Rules of Enjuin (Japanese tradition 16th century C.E.). In modern times, the International Code of Medical Ethics adopted by the World Medical Association in 1949 phrases this obligation as such: "A physician shall act only in the patient's interest when providing medical care which might have the effect of weakening the physical and mental condition of the patient" [7].

Insofar as the objective of clinical trials is to advance science through the randomization of patient treatment, the collaboration of physicians and the involvement of their patients in such trials would seem at first glance to be ethically problematic. The question that looms at the outset of this study is whether clinical

trials may be conducted under ethically acceptable standards. To answer that question we must begin by examining the nature of clinical practice and especially the character of the physician–patient relationship. This reflection will help us to determine whether the collaboration of physicians and the participation of patients in such trials can ever be justified, and if so, under what conditions.

## 2.1 Requirement of Genuine Consent

The startling breakthroughs of biomedical science during the last decades, and the promise of more revolutionary treatments and drugs, obscure the simple fact that medicine is primarily a relationship between two individuals. As Thomasma [8] has pointed out, "medicine is not a theory about the body or how the body works, so much as a theory about practice, about the ways in which physicians and patients, other health professionals, and institutions interact to bring about healing" (p. 246). This interaction begins when a person in a vulnerable state due to physical or psychological illness or distress requests assistance and is admitted to medical care. In doing so, the patient assumes that the physician, as the person in charge of his or her care, will act in his or her best interests and will prescribe the most effective medication or treatment available. What characterizes this relationship is therefore trust and responsibility. The patient trusts that the physician will act in his or her best interest while the physician accepts to shoulder the responsibility of taking care of the patient to the best of his or her abilities.

In the Hippocratic tradition, which still shapes our understanding of the ethos of medicine, the physician–patient relationship is understood in terms of a certain kind of friendship [9, p. 20]. The friendship of the physician (*philantropía*) sees to the well-being of the patient and is expressed through the love for his art (*philotekhnía*), which is healing. While there were many practitioners of the art of healing in ancient Greece, such as magicians and exorcists, the Hippocratic physician loved his art as a *techné*, that is, as an empirically established technical body of knowledge useful to his craft. The Hippocratic Corpus [10, p. 314] states unequivocally the commitment of the physician to empirical science:

> Do not rely on conclusions that result from mere reasoning, but (rely) on evidence. Arguments in the form of plain rhetoric are false and easily defeated. Therefore, you should stick to the facts and scrutinize them, if you are going to acquire faultless capability, which we call Medicine.

Thus, the Hippocratic physician loved his art through his concern for the well-being of his patient and his patient through the practice of his scientifically established craft [9, p. 45]. In other words, the physician loves his patient as a friend because he can come to his aid by applying his craft and knowing that this craft is well founded and likely to produce good results. In this view, science is an essential medium but still plays an ancillary role to the practical object of medical practice, which is the healing of the patient.

In the context of the discussions of the morality of randomized clinical trials, this view of the physician–patient relationship has undergone a radical change. Medical science is no longer seen as primarily an instrument that permits the physician to

exercise his art of healing but as a competing object of his professional responsibility. In other words, it is no longer only a medium but equally an end of the physician's work and thus regulated by an independent set of values. In a very influential article, Lellouch and Schwartz [11] characterize the conflict of interest facing the physician as one between an individual ethics and a collective ethics.

Clayton [12] spells out what these competing sets of values involve. Individual ethics refers, on the one hand, to the duty of the physician "to apply existing knowledge for the best possible treatment of each individual patient." Collective ethics, on the other hand, refers to two duties of the physician: (1) "to acquire new knowledge so that, by that advance, future patients might benefit" and (2) "having acquired that knowledge, to accurately communicate it to other physicians." Gifford [13] notes the existence of the physician's "therapeutic responsibility," which he believes, prima facie, to be incompatible with his collaboration in randomized clinical trials. However, mindful of the benefits that clinical trials bring them, patients might allow the physician to collaborate and would willingly submit themselves to randomized treatments. In this contractual scheme inspired by the philosophy of John Rawls and Robert Nozick, randomized clinical trials could be considered ethical to the extent to which the patients acquiesce to participate and permit the physician to override his or her therapeutic responsibility in order to further a more collective good.

Gifford's contractual approach defers the physician's fiduciary responsibility and places the decision of RCT participation on the shoulders of patients themselves. This approach corresponds well with the insistence upon the informed consent process and the principle of autonomy, which permeates today's ethical climate. This principle of autonomy or permission is widely considered today as the lowest common ethical denominator and the foundation of modern ethics. The reasoning behind one of the major proponent of this view, H. T. Engelhardt [14], is the following. There is a plurality of moral goods, which human beings can pursue and enjoy such as freedom, work, health, pleasure, religious faith, and many others. How these values are ranked in the pursuit of a good life depends very much upon one's political, religious, and philosophical convictions. Furthermore, these different values cannot be arbitrated by appealing to an objective standard, to which everybody can agree. In light of this plurality of moral opinions, it is up to the individual to determine what is good for him or her. A man suffering from prostate cancer might, for instance, want to choose between radical prostatectomy and more conservative methods depending on what outcome he values. If he is younger and still wants to father a child, he might value the preservation of fertility very highly. However, if he has no such thoughts, he might opt for the treatment that offers the best possible outcome in terms of life preservation. It all depends on what values he espouses and what plans he has for the future. Free and informed consent is, in this light, the gold standard of medical ethics.

The principle of autonomy or permission, with its stipulation of free and informed consent, is, in the view of most ethicists, a necessary condition for patient participation in any RCTs, with the possible exception of trials carried out in emergency situations where patients or their next of kin cannot give immediate consent. There is also general agreement that participants should be informed specifically about the relevant details of the randomization process. It is not the quantity of information

given to the research subject that determines whether the consent is free and informed but his or her ability to understand relevant facts in order to make an informed decision. That is why some ethicists talk about "genuine" rather than informed consent [15]. This wording emphasizes the fact that true consent requires health care providers to do their best to communicate accurately and in a way that is understood by patients, volunteers, or relatives. It presupposes that these can understand procedures and risks and react to the limits of their understanding. Moreover, it requires care in detecting and eliminating lack of consent.

While there is general consensus about the necessity of informing patients on randomization procedures as part of the consent process, and prior to trial participation opinions differ on the necessity of informing research subjects about interim data. Those who argue against such disclosure [16] fear that interim data can be unreliable and misunderstood by research participants and the media, which in turn could compromise the completion of RCTs. In a contractual understanding of RCT participation, it is possible to conceive that patients would waive the right to such data, and would accept an "incomplete disclosure" [17] as part of the consent process. Lilford et al. [18] disagree and argue that the praxis of withholding interim data has no public endorsement, is contrary to the spirit of regulations, and is the reflection of a "culture of secrecy and scientific imperialism" that is self-fulfilling. Making interim data available, they argue, would not necessarily reduce recruitment to clinical trials but would most likely increase it because it would enhance public trust in the study. As a result, it would also widen the base of the participants, thus improving the trial's generalizability. The authors provide the example of the second international study of infarct survival (ISIS 2) in which disclosure of improved survival rates of heart attack patients taking clot busting drugs increased recruitment as sceptical physicians became more interested in the interim results. This example shows that more stringent ethical standards do not necessarily decrease productivity. In some instances they could even increase it.

### 2.2 Requirement of Patient Benefit Optimization (PBO)

The Hippocratic model of the physician–patient relationship, where the physician bears the main burden of responsibility and decision making, is considered by many as too paternalistic. Today, patients want to be full-fledged partners in the clinical process, together with the physician. This is all the more important as the physician's loyalty to the patient competes with his or her scientific ambitions. The patient must therefore also fend for himself. Informed consent procedures are one step on the way to establishing more equality between patient and physician. Furthermore, a more democratic approach might give added credence to clinical trials and does not necessarily result in less efficiency. On the contrary, more public trust through greater transparency could result in better recruitment and more generalizability. But there are instances where the requirements of informed consent might not be sufficient to make a clinical trial ethically acceptable.

In addition, the principle of autonomy with its requirement of informed or genuine consent builds upon a model of the patient as a rational agent. This model does not describe accurately how patients make clinical decisions concerning their own welfare. Individuals often behave and make decisions irrationally. To compare treatments is often a complex task, involving a multitude of effect, safety, and con-

venience dimensions. When asked to choose between two treatments, we may therefore—irrationally—prefer treatment A to treatment B, B to C, but C to A, thus violating the transitivity axiom in decision theory. Furthermore, many people have difficulties in understanding small risks. Lastly, the patient is not always able to give informed or genuine consent as, for example, in an emergency or situation of distress. Such a situation may arise when the patient is informed that he suffers from a chronic or fatal disease. He may feel that the physician's time is limited and he may interpret a question about trial participation as an advice or wish from his physician. If the physician clearly communicates that he does not know which treatment is best, and has no advice about study participation, the patient may give his formal consent by signing a piece of paper without really understanding the content and relevance of the information received and thus without acting in a truly free and informed manner.

Because patients are not always capable or even willing to act rationally, and bearing in mind that genuine consent is sometimes difficult if not impossible to retrieve, the attending physician ultimately bears the responsibility of furthering the well-being of his patient and assuring that the trial itself is ethically sound. How can this be assured?

Over the past 30 years, the notion of equipoise has been used to ethically justify physician collaboration in RCTs. It was first used in this context by Charles Fried [19] in 1974 when speaking about the "balance of opinion" among physicians and investigators, when no treatment option in a multiarm RCT is perceived to be inferior to the other or others. From this balance of opinion the term has taken a more psychological turn to connote the "state of genuine uncertainty on the part of the clinical investigator regarding the comparative therapeutic merits of each arm in a trial" [20]. According to this standard, RCTs would be morally justified to the extent to which the clinical investigator can honestly claim a "state of genuine uncertainty" between the treatment options incorporated in the study design.

Most ethicists and clinicians agree that true equipoise rarely exists. Clinical trials are financed and conducted because there are reasons to believe that a new drug or treatment option will improve care, which is also why clinicians choose to implement them in their practice. Notwithstanding this a priori, there might be, however, scholarly discussions in the scientific community about the relative efficacy of a novel therapy. So while absolute or "theoretical equipoise" might not exist, there might still be a nagging uncertainty among investigators and health care providers about the benefits of the different treatment arms. This practical uncertainty or "clinical equipoise" would be the requirement that scientifically justifies such trials. Another term that is used in this context is the ethical theory of "null hypothesis" pertaining to genuine medical uncertainty. The hypothesis entails that clinical trials are justifiable when no consensus exists about which is the better treatment [12, p. 472].

The null hypothesis theory is an easy and questionable justification of RCTs. Consensus among clinicians and researchers about the benefits of a certain treatment versus an alternative is rare, even regarding established treatments. Given that consensus rarely exists, most if not all RCTs could be considered, according to the equipoise theory, as morally justifiable. Moreover, as Lilford [21] has pointed out, even the justification of "uncertainty" regarding treatment outcomes is indeed a

questionable criterion. "Unknown" or "uncertain" is not equivalent to saying that all possible effects are equally likely. Clinicians and investigators always possess some evidence about the merits of the novel treatment or drug before the trial begins. Such information, which can be the basis for drug modeling, is obtained through animal or in vitro experiments, the same treatment in other diseases or, in some cases, even randomized trials. Saying therefore that the effects of the novel treatment are uncertain is certainly ambiguous. The patient might interpret such a statement as meaning that the recruiter has no idea at all about the benefits of the new treatment, which is not the case. Certainty and uncertainty are not absolute terms, and the physician is therefore most likely to have some idea about relative advantages and disadvantages. As Lilford states, "the blanket term of unknown sidesteps any indication of the magnitude of possible effects, reducing the chance that potential participants will be able to appreciate what is really at stake" [21]. In addition, the whole theory of equipoise and ethical null hypothesis is paradoxical because the more an investigator knows about a compound or a treatment the more he would draw away from equipoise. Oddly, it would encourage ignorance.

The notion of equipoise, as used in the debate over RCTs, is therefore problematic because it places too much emphasis on the physician's state of mind. Pleading uncertainty, as Lilford points out, says very little about what is known and what should be told to a patient concerning the merits or drawbacks of a certain treatment option. What is really ethically at stake in RCTs is not whether the physician considers himself or herself in a state of equipoise but whether the patient will benefit more from inclusion in than from exclusion from the trial. This is precisely what the requirement of PBO entails. If the patient stands to benefit personally by inclusion in the trial, the RCT would meet the requirement. If he or she does not, the requirement would not be met.

Studies in which patients in the control arm receive the standard treatment while patients in the experimental arm are given a novel drug expected to be superior would fulfill the requirement of patient benefit optimization. With all patients receiving standard treatment as background medication, it is often acceptable to compare the addition of a new drug with the addition of placebo [5]. But what about placebo-controlled trials where patients in the control arm would be given no pharmaceutical treatment at all? Most ethicists agree that there are conditions when placebo-controlled trials are acceptable and others when they are clearly not. If the ailment under investigation is not serious, and when there is minimal risk and minimal burden for research participants, the use of placebo is generally considered as ethical. A trial studying allergic rhinitis is a good example since this ailment typically does not impair health or causes severe discomfort. Since the possibility of harm is minimal, the benefit derived for the patient in the control arm could be the satisfaction of helping others. Such a trial, despite the use of placebo, could therefore meet the requirement of patient benefit optimization. There are, however, other situations where the use of placebo is unethical. If effective, life-saving, or life-prolonging treatment is available, and if research subjects who receive placebo are more likely to suffer serious harm, a placebo-controlled trial is unethical. The disagreements among ethicists, investigators, and clinicians center on whether placebo controls can ever be used in trials where a treatment known to be effective is available and when there is some potential harm to participants being randomized [22].

The Declaration of Helsinki [23], the most authoritative text on matters of research ethics, is not totally clear on this matter. Paragraph 32 states: "The benefits, risks, burdens and effectiveness of a new intervention must be tested against those of the best current proven intervention, except in the following circumstances: the use of placebo, or no treatment, is acceptable in studies where no current proven intervention exists; or where for compelling and scientifically sound methodological reasons the use of placebo is necessary to determine the efficacy or safety of an intervention and the patients who receive placebo or no treatment will not be subject to any risk of serious or irreversible harm. Extreme care must be taken to avoid abuse of this option." Commentators argue that this wording in the latest revision of the declaration signals a move to a more permissive attitude toward placebo use. This interpretation is motivated by the fact that the 1996 version included the provision that "in any medical study, every patient—including those of a control group, if any—must be assured the best proven diagnostic and therapeutic method" (Paragraph II.3). This sentence, once again, has been eliminated. Despite this omission, the overall tenet of these both versions seems to rule out the use of placebo wherever proven treatment exists. Paragraph 32 in the latest version adopted in 2008 in Seoul, lists two situations where placebo is acceptable: where there are "compelling and scientifically sound methodological reasons," *or* where the condition under study will not lead "to any additional risk of serious and irreversible harm" [23]. What has led commentators to interpret more leniency regarding placebos is the option of the connector "or" instead of "and" between the two provisions. It would seem therefore that the Declaration of Helsinki, in its present version, could be interpreted as saying that the use of placebos for "compelling and scientifically sound methodological reasons" is permissible even when there is an increased risk of serious harm.

The spirit of the text does not go in that direction and the wording of Paragraph 6 ultimately invalidates such an interpretation. This paragraph states that "in medical research on human subjects, considerations related to the well-being of the human subject should take preference over all other interests." However, much of the confusion surrounding Paragraph 32 has to do with the terms "best current proven" or "proven" intervention. Does the text mean "proven" in existence, in a local context, according to the judgment and knowledge of the attending physician, or according to the best interests of the patient? The Nuffield Council on Bioethics [25] suggests that "best proven" should mean "the minimum standard of care that should be offered [in the control arm] is the best intervention available as part of the national public health system."

The Declaration of Helsinki encourages ethically optimized designs that exclude the use of placebos. Consider, for example, a situation where it is scientifically interesting to compare two different drugs, X and Z, which both are available on the market. By giving each patient the drug that is expected to be best for him or her, and assuming that this choice will be different for different patients, it is possible to learn more about the relative merits of the two drugs. Say that X is perceived to be better in patients with mild disease, expressed as a baseline value of a certain covariate below a cut-off $c$, while Y is thought to be better for patients with covariate values above $c$. If the responses are collected, the results from both groups can be modeled as functions of the covariate and extrapolated so that a comparison of the expected responses of the two treatments can be done. As more and more observations are collected, the estimated cut-off will change and treatment practice will

improve over time. This type of trial would be in conformity with the Declaration of Helsinki ethically optimal but, unfortunately, it is not very efficient or viable compared to standard RCTs.

More often than not, it is desirable for methodological and regulatory reasons that the experimental treatment Y is tested against placebo without using X. Can any such trial withstand the PBO requirement? Imagine a trial where participation is beneficial on average but unfavorable for the patients randomized to one of the treatment arms. Say that mortality is estimated to be 10% for placebo, 9% for the "best proven" therapeutic method C, and 8% for a new nonapproved drug candidate X. In order to get regulatory approval for X, the trial would need to prove its superiority versus placebo, which is much easier and cheaper than to show superiority, or even noninferiority, versus C [26]. Therefore, a blinded trial is proposed where ¾ of the patients are randomized to X and ¼ to placebo. The expected death risk for a patient taking part in this trial is ¾(8%) + ¼(10%) = 8.5%, which is lower than the 9% risk experienced by the patients that do not take part in the trial and receive C. This trial would meet the requirement of PBO because, statistically, the patient would benefit more from trial inclusion than from exclusion. It is still, however, very debatable whether the trial would be ethically acceptable because it inevitably exposes certain patients to less than "best proven" treatment. This example shows that while the PBO is a necessary ethical requirement, it is not alone a sufficient requirement for ethically validating a trial.

The example above also indicates that the PBO should not be interpreted as an average utility for all participating patients in the trial but should also be relevant and applicable to every individual participant. Retsas [27] has formulated a thought experiment, which illustrates this point through what we will call the VIP principle:

> Imagine that you are an acclaimed expert on a particular disease and you are invited to offer your services to your head of state. Will the head of state be enticed to participate in a randomised trial leaving his or her treatment to chance, or will treatment be provided on the best available knowledge of the day? It can be observed safely that there are hardly any prime ministers, secretaries of health, doctors, professors, or similar persons who enlist in the ranks of randomised cohorts that serve the progress of medicine!

Retsas' thought experiment is very general and suggests that all RCTs are unethical. While some ethicists have argued that such is the case [28], most believe that it is not. Retsas is also wrong in stating that "doctors, professors or similar persons" do not participate in RCTs. They often do, and the history of medicine is full of examples of clinical researchers risking their lives with self experiments in the zealous pursuit of scientific knowledge. But the point is well taken that physicians seldom recruit VIPs, be they heads of state or their own children, to RCTs. When human life is truly at stake, leaving treatment option to chance, even when there are reasons to believe that the experimental group stands to benefit, is indeed counterintuitive. The fact that a high percentage of drugs tested in phase III clinical trials never reach the market would lead us to exercise extreme caution. The poignant question that Retsas addresses is this: If VIPs are seldom, if ever, randomized by physicians, why should anybody else be? While the VIP principle might be intuitively sound, reason can still ethically motivate RCTs if every individual patient

can be assured that he or she will receive the best possible treatment or its equivalent.

### 2.3 Requirement of Nonexploitation

It has been argued that genuine consent should be a necessary condition for enrollment in a clinical trial. Given that RCTs distort the fiduciary relationship between patient and physician through the latter's participation in what is essentially research and not primarily therapy, the patient's genuine consent is essential in order to reestablish the contractual balance between the two parties. Such a requirement, it has also been argued, is not a sufficient condition for patient enrollment in RCTs. Besides genuine consent, the physician must also ensure that the design of the trial, especially its expected utility, can be aligned with the patient's best overall interests. From an expected utility perspective, the patient should stand to benefit more from inclusion in the trial than from exclusion. There are, furthermore, other cases involving research subjects where the ethical issues involved in the physician–patient relationship are not covered by the two aforementioned requirements, hence the necessity of formulating the requirement of nonexploitation.

A good example of where this requirement is at stake is first-time-in-man (FTIM) trials planned in healthy volunteers. Usually, trial participants are offered economic compensation for the time and discomfort associated with the experiment. Is it unethical to pay these participants for taking medical risks, and would such payment constitute a form of coercion? Assume that there are no discomforts in such a trial, that trial participation is short, that there are no health gains for the volunteers but a slight risk of experiencing an unexpected serious adverse effect. With the possible exception of altruism, there would then be no other reason to participate in the trial other than economic compensation. Assume, furthermore, that a firefighter in the United States is paid to take a small risk in a clinical trial in much the same way that he is compensated for work-related risks. Although it is hard to assess trial risks objectively, it is certainly possible to give some ball-park estimates. Severe adverse events are extremely rare but, as the incident in Northwick Park Hospital in March 2006 shows, they do occur and could potentially lead to death. As a very approximate risk calculation, assume an expected 0.01–0.1 deaths per year globally in FTIM trials, 100 new approved drugs per year, 10 times more drugs tested in humans, and 10 individuals per trial. Then the average death risk for participants in FTIM trials would be about 1 in 100,000 or 1 in 1,000,000. A more careful analysis, using historical data and expert input, may give much better estimates. The risks will also depend on the different kinds of drugs. Hence, there are nonnegligible risks, but these are small and comparable to those taken by some groups as part of their professions. As a comparison, the fatality rate per year in the United States is almost 1 in 1000 for logging workers and fishers and 1 in 4000 for truck and taxi drivers [29]. Healthy volunteers in FTIM studies are paid for their time and for the discomforts they might suffer as a result of the study. From a DA perspective, however, risks and economic gains can be factored in the decision about whether or not to take part in the trial.

The requirement of nonexploitation stipulates that research subjects must be sufficiently free to be able to consent genuinely or, by the same token, to decline trial participation. Generous financial benefits would cast a doubt over certain

persons' capacity to decline an offer of participation, especially those who are economically vulnerable. In this respect, the additional protocol to the Bioethics Convention on biomedical research, adopted by the Council of Europe in January 2005, states very clearly that "no undue influence, including that of a financial nature, will be exerted on persons to participate in research. In this respect, particular attention must be given to vulnerable or dependent persons" [30, Article 12]. The explanatory report of the protocol does not strictly define the term "undue influence" but suggests that it is related to coercion and "may be exerted in particular on a person in a weak or feeble condition, so that very little pressure will overbear the person's will, and make the individual feel that he or she must agree" Furthermore the text specifies that "compensation should not be provided at a level that might encourage participants to take risks that they would not otherwise find acceptable" (Paragraph 64). From an expected utility perspective those who stand to gain the most from trial participation as volunteers, especially the economically weak, would paradoxically be those who are the most discriminated by the requirement of nonexploitation. This short-term discrimination is necessary, however, to protect their long-term interests.

Biomedical research in developing countries is yet another context where the requirement of nonexploitation is especially relevant. Given the accrued risk of exploitation of vulnerable individuals and the potentially huge economic and cultural impact of RCTs in the communities where they take place, the requirement of individual informed consent is not enough to protect the interests of research subjects in this particular context. The European Group on Ethics [31, p. 14] has thus pointed out that "it may be appropriate to seek agreement on the implementation of a research project from persons representative of or invested with a certain authority within the community, or the family." In developing countries, where the capacity of individuals able to consent has been weakened by earlier exploitation or where the principle of autonomy is not widely acknowledged, the consent process must therefore be strengthened by the implication of the larger community. The UK Nuffield Council on Bioethics has also written on the subject and flagged the requirement of nonexploitation as one of three others that should guide biomedical research in developing countries: (1) the duty to alleviate suffering, (2) respect for persons, and (3) sensitivity to cultural differences [25, p. 52].

In most cases, patients in developing countries would receive better medical care while taking part in clinical trials and would therefore generally stand to benefit more from inclusion than exclusion. Seen from an overall benefit perspective, the requirement of nonexploitation could at firsthand discriminate them by placing more obstacles in the way of trial sponsors wishing to conduct such RCTs in developing countries. Such short-term losses would, however, be compensated by creating a better long-term perspectives for individuals as well as developing communities.

The situations detailed above deal with cases where persons able to give consent, and who might wish to participate in a trial, need nonetheless additional protection against possible exploitation at the hands of trial sponsors and collaborating physicians. But what about cases where research might be a condition for treatment? In the United States, the CMS (Centers for Medicare and Medicaid Services) have recently stipulated, for example, that coverage for new users of approved anticancer drugs depends on the willingness of patients to enroll in a clinical trial sponsored by the National Cancer Institute. The CMS policy affects research on tests or treatments

whose efficacy has not been established for the patients being studied. Orentlicher [32, p. 22] argues that such a condition should also extend to research aimed at determining which treatment is most effective when a patient can be offered one of multiple established treatments. Orentlicher's position is motivated by his concern that important studies are being delayed—and medical progress impeded—by difficulties in securing the participation of individuals. In one example he cites, more than half of the patients invited to participate in the study declined with the total recruitment taking twice as long as expected (16 months instead of 8 months).

The Declaration of Helsinki stipulates that participation in any trial is voluntary, that refusal to participate will involve no loss of benefits, and that such participation may be discontinued at any time. Orentlicher's hypothetical protocol would also require voluntary participation and would not deprive the patient of any benefits to which he or she would otherwise be entitled. What he argues for is the individual physician's right to deny care to any patient unwilling to participate in the study. Such a patient would be referred to another physician. The physician–patient relationship is a contractual one and does not oblige the specialized physician to admit any patient who requests medical attention if such medical attention can be received elsewhere and does not represent a danger to the patient in question. Orentlicher argues that trial participation in view of the common good is a valid and ethically justifiable condition for patient care in case the patient can receive equivalent care elsewhere.

Orentlicher's unorthodox position is certainly worth thinking about because it emphasizes that there are societal considerations in any RCT that a strict interpretation of the physician–spatient relationship does not cover. Moreover, in the hypothetical protocol that he proposes, the medical interests of the patients are secured given that the methods being compared are well established and that the patients would be treated by another physician if they declined the offer of participation. However, as we stressed in the beginning, the nature of the physician–patient relationship should be inspired both by the sentiments of friendship and care of the doctor toward his patient and the love for his healing art. It is this *philanthropía* that transcends the terms of different protocols or the provisions of trial designs and that ultimately ethically motivates the physician's *philotekhnía* and hence the possibility of carrying out clinical trials.

## 3 CHALLENGE OF CLINICAL TRIAL EFFICIENCY

Most experts in the field consider that efficiency in clinical development is far too poor. One reason that explains this is the rather simple design imperfections that can still be found in some trial publications. In addition to weeding out these imperfections, trials can be further enhanced by implementing new design methodology and combining them with novel supporting technologies, such as Web-based data capture. The FDA's Critical Path has identified a large number of possibilities that could increase the productivity in different stages of drug development [33, 34]. We will focus here principally on some of the possibilities that relate specifically to the improvement of clinical trial design. After an overview of the current situation (Section 3.1), we will present a DA approach (Section 3.2) to a number of design questions. This paradigm is then applied to the different key

aspects of a trial design. Primarily, we will discuss how each patient can contribute more information (Section 3.3), analyze the optimal size of a trial (Section 3.4), and outline the possibilities that exist to be more adaptive to incoming information (Section 3.5).

### 3.1 Background

The great advances in medicine have contributed significantly to the prolongation of life expectancy during the last century. As part of this, the role of clinical trials during the second half of the century can hardly be overestimated. New pharmaceutical treatments have almost eliminated many diseases and reduced the risks for and consequences of many others.

Trends in productivity are, however, discouraging for drug development. Despite rapidly increasing development costs, the number of approved new drugs has been declining recently. One important reason for the productivity fall is the increased regulatory demands. A further reason is that drug developers try to solve increasingly difficult medical problems. In areas where there are already at least partly effective treatments, a new drug can often not be compared directly to placebo for ethical reasons. To show an effect versus placebo must thus be done indirectly, by testing the new drug and an active comparator in clinical trials, which requires considerably larger sample sizes [26]. Moreover, diseases for which no effective drugs exist are usually much more complicated and difficult to treat.

As many as half of the drugs entering confirmatory studies (phase III) fail [2]. Some drugs, such as the best-selling Vioxx, have also been withdrawn from the market due to safety findings postapproval. Such failures undermine the public trust in medicines and put increased pressure on regulatory agencies. Regulators may react by increasing the demands for safety documentation before drug approval, which will lead to accelerating development costs. A trend can be seen toward a more frequent need for large outcome trials in order to generate enough data to convince regulators of a positive benefit–risk relation. A net result is that, despite huge investments, too few new pharmaceuticals reach the patients in need.

There are a number of hopeful signs, however. First of all, the FDA has clearly recognized the productivity problems and has launched its Critical Path Initiative [33] as a response. This initiative aims at finding innovative ways to improve drug development, in partnership with academia and industry. The Critical Path Opportunity List [34] from 2006 formulates a large number of suggestions, including the use of different biomarkers, innovative/adaptive study designs, and modeling and simulation. It also flags the need to develop methods for indirect comparisons with placebo, in cases where placebo-controlled trials are unethical [26]. Below, we will focus on issues dealing with clinical study design and will not highlight changes in drug discovery technologies and IT per se. It should be noted, however, that the development of information technologies, such as Web-based data capture, is important for the possibility of conducting sequential and adaptive trials in practice.

### 3.2 Decision Analysis Approach to Study Design

As we have noted, the great need for increased efficiency in clinical development is accompanied by new opportunities to improve clinical trial design. A crucial issue

is how to best utilize these possibilities. We will address this challenge by proposing the following systematic, integrated, and quantitative approach:

1. Gather relevant information.
2. Integrate the information into a quantitative model.
3. Define the objectives of the trial.
4. Translate the objectives into a utility function, depending on the trial outcome.
5. Generate a variety of design alternatives.
6. Apply the ethical sift.
7. Simulate the trial outcomes for the interesting designs.
8. Calculate expected utility.
9. Choose the design with maximal expected utility.
10. Check the robustness of the solution to changes in the model assumptions.

The items on this list do not necessarily come in a strict chronological order but are often strongly interrelated. Given that the overall goal is to find a good enough design within the ethical framework, the modeling and DA process will depend on what is needed to accurately answer the design question. Consequently, the proposed approach does not necessarily have to be complicated or time consuming. In many cases, relatively limited work is enough to improve the study design.

This chapter will not describe all the items on the list in depth, as many of them are accurately covered in the existing literature. Much of the literature on modeling is topic specific. A classic text on model building, based in statistics, is Box and coworkers [35]. Pharmacokinetic/pharmacodynamic modeling is described in [36, 37]. Hoppensteadt and Peskin [38] present mathematical modeling for medicine, emphasizing physical processes in physiologic systems but ignoring pharmaceutical interventions. Burman et al. [39] focus on clinical development and provide a shorter, but very similar, version of the list above. Parmigiani [40] treats modeling in medical decision making, taking the perspective of the patient and his treating doctor. This book applies DA and Bayesian methods and describes computer simulations in a relatively nontechnical way. Hunink et al. [41] is an easy read on DA, taking a similar perspective as Parmigiani. It includes a chapter on information gathering (Chapter Clinical Trials Data Management) and notes that subjective components are often needed in the analysis (p. 13 of Chapter "Clinical Trials Data Management"). DA can also be viewed from a management perspective [42] and applied to drug development [43]. A common component of decision analysis and decision theory is Bayesian models. Both Spiegelhalter et al. [44] and Berry [45] provide excellent accounts of Bayesian methods in connection to clinical trials and include sections on ethics. More general texts on DA are Raiffa [46] and the broad overview in Howard and Matheson [47].

Simulations, expected utility calculation, and optimization are quite technical matters but specialized programmers and mathematicians do the job. Literature on random simulations includes [48–50]. Mathematical and numerical analysis can sometimes substitute, and often complement, simulations. Many textbooks cover such areas, including optimization. Although items 7–9 on the list above can be carried out by a sufficiently skilled programmer, the robustness checks should be a

concern to the whole scientific team, in interaction with the programmer. The team, and preferably also experts who have not taken part in the modeling, should change the key assumptions and look at how these changes affect the conclusions. If the solution is very sensitive to the value of a parameter, there is a strong indication that more knowledge should be sought regarding its true value. Renewed information gathering or focused experimentation may be indicated.

Naturally, the utilities may be quite different depending on what perspective you take. From a patient perspective, and in order to comply with the spirit and the letter of the Declaration of Helsinki, placebo should preferably not be used. FDA and European regulations stipulate, however, that a positive effect has to be demonstrated versus placebo, by direct or indirect comparison. Finally, a trial sponsor has to consider the return on investments. Although there are complementing company perspectives, we will take the net present value (NPV) as a proxy for the company utility. Profit maximization from the company's side must, however, be made under the constraints outlined above. Among the possible ethically compatible designs, the company will try to maximize the expected NPV for the project or, more generally, for the company. The value of the project will reflect also the regulatory hurdles and the possibilities of convincing payers about the cost-effectiveness of the drug.

Let us now study the key elements of clinical trial design. The following three subsections will address different aspects of this question.

### 3.3 Optimizing Information per Patient

The general aim of all experiments is to reduce uncertainty. The obvious way to decrease the uncertainty of trial results is to increase its sample size. In Section 3.4, we will apply DA to the problem of finding the optimal sample size. However, the most cost-effective way of retrieving trial information is often to reduce the variance for each patient. There are a number of ways to do this such as devising more than one treatment and several measurements per patient, choosing a more informative response variable, and choosing a patient population with a larger response.

***Covariates and Multiple Measurements*** For many chronic diseases, there is a response variable [e.g., cholesterol level, forced expiratory volume ($FEV_1$), subjective symptoms, or quality of life (QoL)] that fluctuates over time. Technically, we will assume that the variable follows a linear normal model, implying a linear dependence on covariates as well as normally distributed residual terms. The variability in the response variable during treatment has several different causes. It is standard procedure to include the baseline value of the response variable as a covariate in the linear model, together with other potentially predictive covariates. This will reduce the variability due to explainable differences between patients and may lead to considerably higher efficiency of the trial. These covariate adjustments are part of good statistical practice and concern more the analysis than the study design. Some of the other ways of reducing variability require larger modifications of the study design.

A straightforward example of how DA can be used concerns the decision of how many measurements should be taken per patient. One cause of variability that is not handled by covariate adjustments is the day-to-day fluctuations within each

patient. This variability can be reduced simply by taking measurements on different days and using the average of the observations as the response variable. Many studies collect the necessary information without using it in the analysis. Say, for example, that the objective (item 3 on the list in Section 3.2) is to estimate the primary variable in the most cost-effective way as possible. We then proceed by setting up the utility function (item 4). In this case, the cost per information is a function of the number of measurements $M$ per patient. Whether more than one measurement should be taken is essentially a question of how much of the total (unexplained) variability is attributed to day-to-day variability and how much it costs to reduce it. In a straightforward model (item 2), the variance of the average for a patient is proportional to $1 + V/M$, where $V/(1 + V)$ is the fraction of the observation variance that is attributed to day-to-day variability. Assume (item 2 again) that the cost per patient is proportional to $1 + CM$. As information is the inverse of the variance, the cost per unit of information is proportional to $(1 + CM)(1 + V/M)$. The number of measurements, $M$, can easily be chosen (item 9) to minimize this cost/information ratio, given that the value of the parameters can be estimated (modeled) from existing information (item 1).

Say, for example, that the cost per patient is \$11,000 if only one measurement is taken and that the additional cost per extra measurement is \$1000. Assume as well that 50% of the total response variance of 200 units is due to day-to-day variability. The cost and variance per patient are then $10{,}000(1 + 0.1M)$ and $100(1 + 1/M)$, respectively. The cost/information ratio, $1{,}000{,}000(1 + 0.1M)/(1 + 1/M)$, is minimized if $M = 3$ measurements are made. The cost per patient increases by 18% if $M = 3$ compared to $M = 1$, but the variance per patient decreases by as much as one third. Consequently, the sample size can be decreased by one third, from 200 to 133 per arm if a standard error of 1.0 is to be achieved. The cost per unit of information is reduced by 22%; in a two-arm study the total cost decreases from \$4.4 million to \$3.52 million. A robustness check (item 10) indicates that $M = 2$ or $M = 4$ give most of the benefit that is achieved with $M = 3$, and that $M = 2$ is a viable solution for a range of values for the parameters, for example, if the cost per measurement is twice as large as originally assumed.

This example does not indicate that the number of measurements should generally be increased. In other situations the analysis would indicate that costs should be cut by decreasing the number of visits. The point is that the efficiency of a design is often a trade-off between estimation precision and costs. By clearly defining the trial objective, integrating information about variability and economical costs, and quantifying a utility function, the decision problem is clarified. This kind of reasoning is considerably more far-reaching than just deciding on a hunch the number of measurements. In the example above, there could be complications given that the true underlying effect is changing over time, and that there is a nontrivial correlation structure between observations taken on different days. Typically, the effect is increasing toward a steady-state value and the correlation between two observations decrease with the time between the observations. The solution to both these problems is essentially the same: Model the time–effect process and the variability structure and then apply DA to the problem of finding the optimal sample scheme and test variable.

A common way to waste information is to dichotomize data, that is, to replace a continuous response with a zero–one variable in order, for example, to classify

patients as "responders" and "nonresponders" and ignore the rest of the information regarding the response. Occasionally, there are good reasons to classify patients as responders or nonresponders, based on whether a continuous response variable is above or below a specified cut-off value, and base the primary analysis of the constructed zero–one responder variable. However, in most situations, a direct analysis of the original continuous variable gives much more information [51, Section 8.2.4]. If the treatment effect is small, for example, the efficiency gained by using original data is about 57% when the patient population is divided in two approximately equally sized groups based on a normally distributed variable. The efficiency is more than doubled and almost threefold when the dichotomous population split is 80%–20% and 90%–10%, respectively. It is usually possible to model the distribution of the response (item 2), and then the effects of dichotomization are easily investigated by simulating (item 7) the power for the alternative response variables.

***Cross-Over Designs*** The between-patient variability is completely eliminated if the patient can serve as his or her own control. This is the idea behind cross-over trials, where two or more treatments are given to each patient during different periods. Such designs are well studied [52, 53] and have been utilized systematically in some areas for many years, especially in phase I trials of pharmacokinetics and also for patient trials in some specific medical indications. However, there are possibilities of expanding the scope of these designs considerably in the future. When a cross-over design can be applied, the efficiency of the trial can normally be reduced drastically. The number of patients in the trial can often be reduced by considerably more than 50%.

There are some clear limitations to the use of cross-over designs, however. Cross-over trials are only possible for chronic diseases and obviously not suitable to investigate, for example, mortality. Their potential is largest in proof of principle and dose finding and for discriminating against similar competitors. They are best suited when the treatment response is relatively fast (asthma, lipids, some lab values, etc.). Carry-over effects have been seen as an important problem. However, there are in many cases possibilities to handle such potential effects by wash-out periods, statistical corrections, or pharmacological modeling.

When a cross-over design is considered as an alternative to a parallel group design, the usual tools of modeling, simulation, and DA can be of help. Using available information (item 1) in terms of earlier trials with the same and similar drugs, between-patient and within-patient variances can often be estimated or at least guessed. The time–effect curve and potential carry-over effects can be modeled in a similar way (item 2). Based on some models, it is possible to predict (item 7), often via simulations, the likely effects in the planned trial. There will often be trade-offs (items 4 and 9), for example, between the treatment duration and factors such as inclusion time, potential bias, and variability. A cross-over design will probably have a shorter inclusion period, as the sample size is lower, but a longer total treatment time. It is sometimes reasonable to shorten the treatment time per period, although this may lead to the steady-state effect not being fully reached.

Cross-over trials make it possible to assess whether there is a between-patient variability in the relative treatment effect. It may even be that treatment A is better in some patients while other patients are better off on treatment B. Parallel trials cannot assess such individual differences in effect between patients with similar

prognostic variables. One extreme version of the cross-over design is worth mentioning in this context. A trial may be conducted in one single patient, exposed to treatments A and B in a series of treatment periods. This design appears to be quite natural. It resembles what a patient suffering from migraine attacks would do to find out which "treatments" are causing the attacks. She occasionally eats chocolate, drinks wine, goes out in heavy sunshine, and notices when the migraine problems occur. Gradually, she will understand her personal risk factors and avoid them. The design, called *N*-of-1, can be much more rigorous, involving blinding and randomization to two or more treatment groups, comparing two or more pharmaceuticals [52, Section 7.4].

*N*-of-1 trials may be attractive from an ethical perspective when the aim of the experiment is to find the best treatment for the individual patient, and DA is used to find the optimal criterion for when the testing should stop and the patient receive the better treatment henceforth. However, the signal-to-noise ratio is often too poor to allow firm conclusions on the best treatment for an individual. A combination of data from *N*-of-1 trials in several patients can be performed in order to estimate treatment differences more precisely and also estimate how a large percentage of patients would benefit from each treatment.

### 3.4 Optimal Amount of Information to Collect in Trial

Having discussed how to optimize the information gathering for each patient, we will now turn to the problem of choosing the optimal amount of information to purchase, that is, to determine the sample size. Clinical trials are commonly dimensioned by specifying a least clinically relevant effect, taking this as the alternative hypothesis, and then calculating the sample size that gives, say, 90% power of detecting any effect. This approach can be severely misleading, we think, as it ignores all relevant information except the least clinically relevant effect. We will sketch how the knowledge and uncertainty regarding effect and safety, regulatory demands, price, market size, and study costs could all help to find the best sample size. However, let us first analyze the notion of "the least clinically relevant effect." If you have to choose between two drugs with known different effects but identical safety profile, price, dosing, tablet size, and the like, which would you choose? If your 1-year risk of dying is 1% with drug A and 1.1% with drug B, you would clearly choose A. Will the choice be different if the risk is instead 1.001% with drug B? Our conclusion is that all differences are "clinically relevant." The question about which drug to prefer arises only if both drugs have relative advantages in different aspects. For the patient, there can be a trade-off between effect and safety, for the payor between effect (and safety) and cost.

For the drug developer that tries to maximize the expected net present value (ENPV), study sizing is a trade-off between generating enough information regarding effect and safety on one hand and the cost of the trial on the other. A related and even more fundamental problem is whether any investment at all should be made in developing the drug or if the project should be terminated immediately. It is very complex to optimize a complete clinical development program, as the optimal design of a later phase depends on the data from the earlier phase, and the optimal design of the earlier phase depends on how the results from this phase will be used for designing the later phase. The principle solution to the problem is backward

induction [54], where one starts by analyzing the last phase, given different possible outcomes of earlier phases. After finding how phase III should be designed as a function of the information from phase IIB, phase IIB can be optimized. This process can in principle be carried back to even earlier phases, although computational difficulties and specification of the complex problem may be obstacles.

Consider the problem of dimensioning a phase III trial, assuming that supportive evidence exist and that one successful phase III trial will be enough to get the drug approved. Generally, the utility, as a function of the sample size $N$ of the trial, is the gain by running the trial minus the cost for doing so. The cost can often be put rather directly in monetary terms. However, the personnel resources may be limited and hard to expand rapidly. Consequently, one may have to consider that if the phase III trial is run, other projects may be delayed or stopped and the net consequences of this should be factored into the cost analysis. As the sample size affects the possible time to market introduction, the time delay may be viewed as a cost. Time effects are, however, related to the trial outcome and are easier to analyze as part of the gain function.

The gain can be complex to analyze, although some market value calculations are routinely done in current practice. The simplest model is to say that the drug is approved if and only if a statistically significant effect versus placebo is shown in phase III, and if it is approved the commercial value is a certain known amount. This model can easily be improved by modeling how the market value will decrease with a delay in study ending time as a result of an increased sample size. There are, however, other factors, such as the market value's dependence on the trial results, that are harder to model. It is often too simplistic, although common, to assume a fixed market value if the drug is approved without considering how good the trial data are. One way of modeling the sales of a drug is to start by analyzing the decision analyses that the patient is doing together with his or her physicians. What is required to choose the new drug in terms of estimated effect, standard error for the effect estimate, safety, price, and the like? Pharmaceutical companies often perform limited market research about such questions by asking physicians to compare different hypothetic drugs. Individual treatment decisions could then be aggregated to form an effect–sales model. It is likely that historical data on, for example, how fast a market is penetrated have to be added in order to find a suitable model.

The commercial and cost models together give a utility function. The design alternatives are all possible sample sizes, including the possibility of stopping the project and not run the trial. Regulators may have requirements for a minimal sample size in order to get enough safety information. With a model for the effect of the drug and for how large the uncertainty is, the trial results can be predicted, by numerical methods or simulations. It is often important to consider the uncertainty in the effect estimate and run Bayesian clinical trial simulations. Combining predicted trial results with the utility function, the expected utility can be calculated for each sample size, and the optimal sample size can be found. The expected utility is relatively flat around the optimum, indicating that the exact sample size is not crucial. The ENPV can be very sensitive to such changes in assumptions concerning costs and gains. However, given that it is optimal to run the trial, the sample size is typically relatively robust against such changes, meaning that the same sample size often gives an ENPV close to the optimal ENPV.

The time to market is essential. If there is an indication that the sample size should be increased, one might therefore consider including a larger number of centers. In analyzing this option, both direct costs and the risk for reduced quality, leading, for example, to a larger unexplained variability, should be considered. The optimal size of an experiment is discussed by Lindley [55] and a review on applications to clinical trials is provided by Pezeshk [56].

***Commercial Limitations*** Medical research will likely look for smaller and smaller improvements in many therapeutic areas. Smaller effect differences than what most historic studies have set out to detect may still be of great importance. The vast majority of mortality trials have been dimensioned to detect risk reductions of 20% or more. However, a treatment with 10% additional reduction in, for example, cardiovascular mortality, would of course be of great value. The problem is that smaller effects call for larger trials. The sample size is, at least approximately, proportional to the square of the relative treatment effect. Thus, looking for a risk reduction of 10% instead of 20% will mean that four times more patients are needed in the trial. While the cost for a trial is approximately quadratic in the effect size, the benefit, in the number of spared lives, say, is linear. Thus, small enough relative effect sizes will not be found by clinical trials, although they may translate into a large number of deaths.

Assuming rational payors, the commercial gain of introducing a new pharmaceutical will always be lower than the societal gain, as the price will always be lower, at least for some payors, than the willingness to pay. There are, consequently, research projects that would give a good expected return-on-investment for society, although they would never be run by commercial interest. Noncommercial research therefore has a clear value.

### 3.5 Adapting to New Information

For both economic and ethical reasons, it is clearly desirable to adapt the design of a clinical trial in response to accumulating data. Interim data may show, for example, that there is a clear difference between the treatments. The trial can then be stopped, permitting the patients in the control arms of the study to stop receiving the inferior treatment. Alternatively, interim data may indicate that a proposed treatment has no clear benefit over the placebo. The trial can in such a case also be stopped for reasons of futility.

***Group-Sequential Designs*** The most well-known example of adaptive designs is the classic group-sequential design [57, 58], which permits a number of interim analyses to be conducted. It allows for the trial to be stopped if interim results are convincing enough according to preset criteria. As a statistically significant result can be obtained both at interim analyses and at the preplanned full sample size, the critical limits for when to claim significance must be adjusted. The result is that a group-sequential trial has to have a somewhat larger maximal sample size than a fixed-size trial if the same power should be obtained. This is the price to pay for the possibility that the trial sometimes can be stopped much earlier than in a trial without interim analyses. With a reasonable group-sequential design, the expected sample size is decreased. Consequently, the cost related to the number of patients

is on average decreased. Among the drawbacks of a sequential design are the cost for the interim analysis per se. Given these costs, it is straightforward to simulate trials and calculate the expected total cost to find which design is best. One can investigate whether it is optimal to include interim analyses, when they should come and what the critical limits for significance should be. There are some additional drawbacks, such as problems with overrunning, that is, that additional trial data may be obtained after an interim analysis that suggested a trial termination. Such data may potentially change the conclusion in the trial. Still, it is possible to simulate this problem and factor it into the DA.

***Flexible Designs*** From a DA perspective, the optimal design of a trial may change during a trial if external information is received that changes the utility function or the effect/safety model. Examples of such information is the approval of a competitor drug or the finding of unexpected safety problems in substances with similar chemical properties as the one being developed. It is therefore desirable to be able to change the design during the conduct of a trial. An article by Bauer and Köhne [59] in 1994 gave the impetus to research in flexible designs that allow several types of design modifications in response to interim data or external information. According to Müller and Schäfer [60], "design changes may include increase or reduction of the sample size and of the number and time points of interim analyses, and even changes of the type of statistical test, of the outcome variable, or of the null-hypothesis." Their stand is that such changes do not have to be preplanned. However, if such flexible designs are getting acceptance and penetrate clinical trial practice, it will constitute a fundamental change compared to the hitherto dominating methodology. Preplanning has always been one of the cornerstones of controlled clinical trials and a basis for the classical statistical analysis of data. Other authors, including Bauer and Köhne [59] in their original work, have been more moderate than Müller and Schäfer [60] regarding when and how flexible designs could be used. The EU reflection study [61] on adaptive designs is quite restrictive to flexible design changes, especially in confirmatory studies.

Sample size reestimation (SSRE) has attracted the greatest interest among the flexible designs. The sample size may, for example, be increased in order to achieve more statistical power if the interim estimate of the treatment effect is lower than anticipated. The fundamentally new technical idea behind flexible designs is to tentatively consider different stages of a trial as different trials altogether. One $p$ value is calculated for each stage in isolation. These $p$ values are then combined into a $p$ value for the complete trial, by weighting together the stagewise $p$ values. The type I error can be guaranteed, for essentially all kinds of design modifications, as long as the weight for each stage is determined independently of the data from that stage.

The weighted inference is controversial. Jennison and Turnbull [58] have suggested that an adequately developed group sequential design is preferable to an adaptive SSRE that only depends on interim data. The flexible design has, however, the advantage of being able to be modified according to information external to the trial. Another problem with the methodology proposes by Bauer and Köhne [59] is that equally informative observations may receive unequal weight in the analysis, depending on which stage of the trial they are collected. This feature has been criticized for violating the sufficiency principle, leading not only to inefficiency [58] but also in extreme cases to erroneous conclusions [62].

Our tentative conclusions are that careful preplanning of trials is crucial, that there can occasionally still be a genuine need for flexibility, that the weighted test is questionable but that a modification of this test could be of value. The works on flexible designs mentioned above have been based on classical, frequentist statistics. Bayesian statistics can more naturally incorporate sample size modifications and other design changes. Such modifications can be useful in earlier phases but may not be accepted in the confirmatory phase.

## 4 DISCUSSION AND CONCLUSIONS

Since World War II, the number of clinical trials has increased rapidly. The importance of these trials can hardly be underestimated. The medical needs continue to be manifold. Despite the clinical needs and the steady increase in the number of clinical trials carried out, there are factors that could threaten their future. In this chapter, we have highlighted the problems concerning ethics and efficiency. Although RCTs represent the gold standard in clinical development, there are alternatives. Observational studies and historic controls can give valuable information, even if their interpretation is not as straightforward as blinded clinical trials. Preclinical experiments and modeling can also substitute some trials.

Clinical trials should be performed in an ethical manner. Failure to do so is not only unethical, per definition, but it also jeopardizes public trust in clinical development. A patient is unlikely to give informed consent unless he or she is convinced that the physician will put the patient's interests first. The concept of informed consent is a fundamental requirement that we have highlighted. In the rare situations where informed consent cannot be given by the patients themselves (studies on unconscious patients or children), the informed consent should instead be given by a guardian *on behalf of and in the interest of* the patient as soon as possible. Likewise, the physician should see principally to the best of his or her patient first and only secondarily to the interests of science. Thus, when the physician also acts as an investigator, he or she is still personally responsible for ensuring that the patient's best interests are safeguarded during trial participation. In addition to genuine consent and patient benefit optimization, an ethical requirement of nonexploitation is needed. Additional requirements may be indicated to cover issues about, for example, payment and trials that are beneficial on average but include nonoptimal treatment arms. While patient enrollment is the responsibility of the physician, the ethical standard of clinical trial is the common responsibility of the investigator, the ethical committee, the sponsor, and the personnel responsible for the planning and the execution of the trial. Personal responsibilities should be stressed to avoid the risk that all actors put the responsibility on someone else, leading to unethical and risky trials.

Ethical requirements constrain trial design, in particular the treatments that can be tested. Depending on the situation and background information, these constraints will sometimes complicate or even obstruct clinical development. Within these limits there are, however, considerable possibilities of optimizing designs that can also be efficient. Several features of a trial design should be considered in the process of trial optimization, such as sample size, patient population, and treatment duration. There are also great possibilities to apply alternatives to the standard

parallel-group nonadaptive design and there is a continuing methodological development. How to choose between all the available options is perhaps the major challenge. Consequently, we anticipate that the most significant changes in trial design will take place in decision process rather than design methodology per se. Model-based drug development is already receiving considerable attention. Still, modeling and DA are clearly underestimated.

## 1 BACKGROUND

### 1.1 Why Is Proof-of-Principle/Proof-of-Concept (PoP/PoC) Crucial in Drug Development?

Drug development is complex, costly, and time consuming. After decades of fruitful endeavors leading to novel therapies that radically changed the way we treat human disease (e.g., β-blockers, proton pump inhibitors, SSRIs, HMG-CoA reductase inhibitors, and many others), the pharmaceutical industry began to face increasing and significant challenges. Everyone who is involved in drug development is well aware of issues such as the "innovation gap," "productivity decline," and "late-stage attrition." Indeed, these issues have been on the agenda for some years now and have triggered waves of new paradigms in drug development. Essentially, the pharmaceutical industry has been investing more and more resources in developing new drugs, but this has not been translated into more successful medicines, that is, medicines that are approved by the regulators and well-received by the market. In other words, the output from the R&D machinery has not kept pace with spending. This productivity decline is illustrated in Figure 1 showing escalating drug development costs with no parallel increase in the number of regulatory approvals. The average cost of bringing a new compound to the market is in the neighborhood of $1.3 billion [1] and the overall clinical success rate is 11% [2]. A nearly 50% attrition rate in phase III is still plaguing pharmaceutical companies [2]; and there is no clear evidence that it is on the decline. Late-stage failures are severe blows that hurt large pharmaceutical companies and might ruin smaller ones, and it is in this context that the importance of early PoP/PoC becomes apparent. Drug developers need to ascertain that only compounds with a high chance of success are selected and progressed through the development process. Although most pharmaceutical companies are trying to adopt "kill early" approaches, this is often hampered by the lack of reliable "killer experiments" and the fear of erroneously discarding valuable assets. For smaller companies such as many in the biotechnology sector, which often lack the resources to take compounds through full clinical development, a positive PoP/PoC significantly improves the chance of finding a partner or successfully licensing out the compound. Regardless of company size, a robust early PoP/PoC has become a key component in contemporary drug development.

### 1.2 Definitions

A human PoP/PoC trial is simplistically a trial that provides indications that the compound might work in the intended therapeutic area. Some companies distinguish between a PoP trial in which the pharmacological principle has been

***FIGURE 1*** *Escalating R&D spending with no increase in output (FDA drug approvals): 2004–2007 approvals include new biologics. (Source: FDA and Pharmaceutical Research and Manufacturers of America, Pharmaceutical Industry Profile 2008, PhRMA, Washington, D.C. March 2008).*

demonstrated in humans (healthy subjects or patients), usually with the use of a biomarker and a clinical PoC trial where early signs of efficacy are detected, based on solid clinical endpoints or validated surrogates. However, PoP and PoC are often used interchangeably. A broad definition has been proposed by fifth EUFEPS Conference: "A human trial that provides scientifically sound evidence supporting the postulated effects of a new therapeutic drug product, where effects may be relevant pharmacological action or a change in disease biomarkers, established surrogate endpoints, or clinical outcomes, and be beneficial and/or toxic in nature" [3].

## 1.3 When Should PoP/PoC Be Established?

As indicated above, spiralling development costs and high attrition rates are forcing drug developers to search carefully for signs of efficacy and potential safety concerns as early in the development process as possible. It is common practice today to conduct a PoP/PoC trial as soon as phase I trials have provided evidence that the compound appears be to reasonably safe in healthy subjects and possesses pharmacokinetic characteristics that are in line with projected clinical use. As shown in Figure 2, a PoP/PoC trial is conducted as a part of phase II.

The PoP/PoC is located at a most crucial "go–no go" decision point in most pharmaceutical R&D organizations. Once PoP/PoC has been established, drug developers (and investors) feel more confident to invest in the subsequent, more costly clinical trials.

***FIGURE 2*** *Location of PoP/PoC in the drug development process. ER, Exposure–response; NDA, new drug application; MAA, marketing authorization application.*

Although PoP/PoC is often linked to a single trial that provides a dichotomous "yes or no" answer, it is more prudent to think of PoP/PoC as a package of key data that have emerged during the early exploratory phase of development. Thus, a positron emission tomography (PET) study in healthy volunteers may provide evidence that a certain compound crosses the brain–blood barrier and binds to a specific receptor in the brain. A human model (Table 3) may show that the compound is effective in a disease-like setting. Pharmacokinetic/pharmacodynamic (PK/PD) modeling of preclinical and human data is used to characterize the exposure–response (ER) relationship and ensure that safe doses are potentially efficacious. Finally, the integrated data package from all of the above provides a reasonable level of confidence to pursue development, that is, a PoP/PoC-based "go decision."

## 2 CONSTANTLY IMPROVING TOOLBOX FOR POP/POC

Despite the serious issues facing the pharmaceutical industry, the scientific advances in biosciences (chemical and imaging biomarkers, pharmacogenetics and pharmacogenomics, proteomics, toxicogenomics, metabonomics) are providing drug developers with useful tools to explore the potential clinical utility of new targets and novel therapeutic agents. These areas of research have become independent disciplines and there is a wealth of literature on each of them. Since biomarkers constitute a key component in PoP/PoC paradigms, they are discussed in some detail next.

## 3 BIOMARKERS IN POP/POC TRIALS

The National Institutes of Health (NIH) Biomarkers Definitions Working Group has defined a biomarker as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention" [4]. Although biomarkers have been used in drug development for decades, the new potential of using biomarkers for regulatory purposes (label claims) [5] has intensified the efforts to develop biomarkers that are accepted for ordinary and accelerated approvals. Regulatory initiatives, most notably the Food and Drug Administration's (FDA's) Critical Path Initiative have opened new avenues for collaboration between academia,

**TABLE 1 Examples of Biomarkers Accepted by FDA as Surrogate Endpoints**

| Condition | Surrogate |
|---|---|
| Ischemic heart disease | Plasma cholesterol |
| Stroke | Blood pressure |
| Osteoporosis | Bone density |
| Diabetes mellitus | HbA1c |
| Prostate cancer | Serum testosterone |
| HIV/AIDS | HIV-RNA load and $CD4^+$ cell count |

pharmaceutical companies, and regulators aimed at facilitating innovative approaches in the development of novel medicines [6]. A key area in the Critical Path Initiative is biomarkers with a special consortium focusing on the qualification of biomarkers for regulatory decision making. Qualification of biomarkers refers to the process of linking a biomarker with biological processes and clinical endpoints [7, 8]. The highest level of qualification of a biomarker is surrogacy, that is, when the biomarker can substitute for a clinical endpoint [7, 9]. Table 1 shows examples of biomarkers that have been accepted by the FDA as surrogate endpoints.

It should be underscored that while surrogate endpoints and other "valid" biomarkers can and should be used in PoP/PoC trials when available, early clinical development is an exploratory phase, and less well-qualified biomarkers can provide valuable information for internal company decision making. For example, "distal biomarkers"—relative to the clinical endpoint—can be very useful in confirming the pharmacological activity of a given compound in humans [10]. This is especially valuable in two situations: the selection of follow-up or backup compound when the "pathfinder" has demonstrated clinical utility; and the validation of a novel mechanism of action with an uncertain role in the pathogenesis of the disease. Lack of clinical efficacy despite adequate pharmacological effect would disqualify the mechanism of action and stop the development of similar compounds. Also, biomarkers can be very useful in establishing the ER relationship preclinically and translating that relationship into the clinical phases of development (the concept of translational science), facilitating dose selection in PoC studies and beyond [11]. Good examples of the use of biomarkers in early clinical development have been described by Kuhlmann [12]. These included the use of ex vivo inhibition of cholesteryl ester transfer protein (CETP) in healthy subjects to establish the pharmacological activity of a CETP inhibitor, the use of leukotriene D4-induced bronchoconstriction to establish PoP and dose–response in healthy subjects for a leukotriene receptor antagonist for asthma, and the use of pupillography as a marker for effects of 5-hydroxytryptamine 1A (5-HT1A) compounds.

## 4 PHARMACOGENOMICS, PROTEOMICS, AND METABONOMICS

The concept of identifying genomic [single nucleotide polymorphisms (SNP), haplotypes, ribonucleic acid (RNA) expression signatures], proteomic [protein profiles in plasma, cerebrospinal fluid (CSF), synovial fluid, etc.], and metabonomic (metabolite patterns in body fluids) markers that identify patients who are likely to respond to treatment and/or to develop serious adverse drug reactions is very exciting albeit

**TABLE 2 Examples of Valid Genetic/Genomic Markers Predicting Clinical Response or Specific ADRs**

| Marker | Drug | Clinical Relevance |
|---|---|---|
| Her2/neu overexpression | Trastuzumab | Only patients with tumors overexpressing Her2 are eligible for treatment. |
| Philadelphia chromosome (Ph1) | Busulfan | Poor response in patients with AML who lack Ph1 chromosome. |
| PML/PAR alpha gene expression | Tretinoin | Clinical response to tretinoin in patients with APL have not been observed in the absence of the genetic marker. |
| Thiopurine methyltransferase (TPMT) variants | Azathioprine | Increased risk of myelotoxicity in patients with low or absent enzyme activity. |
| HLA-B*1502 allele | Carbamazepine | Risk for serious dermatologic reactions in patients positive for the allele. |
| G6PD deficiency | Rasburicase | Drug is contraindicated in patients with G6PD deficiency due to the risk of severe hemolysis. |

AML, acute myelogenous leukemia; APL, acute promyelocytic leukemia.

extremely challenging. There are few examples of valid genomic markers that predict clinical outcomes [responder vs. nonresponders; adverse drug reaction (ADR) prone genotypes] and that have been accepted by the FDA as part of the label (Table 2). A comprehensive list of valid genomic biomarkers in the context of FDA-approved drugs is available [13].

However, in the context of early clinical development of novel compounds acting on nonvalidated targets, the identification of such markers remains a major hurdle to overcome. Roses and colleagues described some examples of the use of early pipeline genetics to predict efficacy and side effects of new compounds [14]. These included the identification of gene variant candidates related to efficacy in a phase II obesity drug trial, and the early discovery of the genetic basis (CYP 2C9 polymorphisms) of some of the side effects of the kinase inhibitor lapatinib (Tykerb). The authors rightly underscored that such early findings can only be used to generate hypotheses and that the validation of these markers should await larger clinical trials [14]. The limitations of pharmacogenomic predictor discovery in early clinical trials are discussed in Pusztai [15].

Needless to say, this field is still in its infancy, and the ultimate impact of the "omics revolution" on expediting drug development and reducing attrition rates remains to be seen.

In many pharmaceutical companies, default banking of samples from clinical trials for future genetic/genomic analyses is becoming common practice, although this is sometimes challenged ethically and legally. Since genetically determined variability in drug metabolism, most notably involving CYP 450 enzyme system, impacts significantly on the pharmacokinetics and consequently pharmacodynamics of many drugs, it is prudent to obtain relevant genotypes in healthy volunteers and patients in early clinical trials of compounds known to be mainly metabolized by CYP 450 isoenzymes, primarily CYP 2D6, CYP 2C9, and CYP 2C19. This would be useful if unexpected PK/PD profiles are observed and potentially reduce the risk of selecting inappropriate doses in PoP/PoC trials resulting in erroneous go–no go decisions.

## 5 IMAGING

Advances in medical imaging present a great opportunity in drug development. A number of different imaging technologies are available. These include computed tomography (CT), magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), positron emission tomography (PET), and single photon emission computed tomography (SPECT). If adequately qualified, imaging biomarkers can be very helpful in the early phases of clinical development. Early evidence of biological/pharmacological activity of a new compound as well as useful pharmacokinetic profiles for future dose selection can be obtained. For example, using fluorodeoxyglucose PET (FDG-PET), it could be shown that glucose metabolism was reduced in gastrointestinal stromal tumors in patients treated with imatinib mesylate (Gleevec), indicating an early response that preceded tumor size reduction (on CT) by weeks [16]. The development of a new antidepressant was terminated based on the finding that the compound lacked specific receptor binding, as shown by cerebral PK imaging [17]. Other good examples of the use of imaging in early clinical trials in different therapeutics are described by Pien et al. [18]. The potential advantages of imaging techniques in the different phases of drug development have recently been reviewed by Strack [19].

## 6 PHARMACOLOGICAL AND NONPHARMACOLOGICAL MODELS FOR POP/POC TRIALS

### 6.1 Pharmacological Models in Healthy Volunteers

In these models, a pharmacological agent, for example, scopolamine is given to healthy subjects to induce symptoms typical of the targeted disease, in this case dementia (cognitive impairment with deterioration of episodic memory and attention) [20, 21]. Compounds with cognition-enhancing characteristics would reduce these symptoms [22], providing early evidence of potential clinical efficacy. Pharmacological models are often used in psychopharmacological research, and, if adequately adapted, some of them can potentially be useful in early clinical development of psychotropic drugs (see [23] for a review). Asthma is another therapeutic area where pharmacological provocation tests in healthy volunteers; using, for example, methacholine [24, 25] or leukotriene D4 [26] are utilized to demonstrate a pharmacological activity and capture early signs of potential clinical efficacy. It should be pointed out that unless the model used involves a mechanism that is relevant for the pathophysiology of the disease, a positive effect of a new compound in the model merely demonstrates a pharmacological antagonistic activity and does not provide early evidence of efficacy in the targeted disease. For leukotriene receptor antagonists, a class of drugs that target a mechanism known to be involved in the pathophysiology of asthma, a reduction of bronchoconstriction could be demonstrated in the leukotriene challenge as well as in other provocation models using, for example, allergens, methacoline, and ultrasound-nebulized distilled water [27, 28].

If models are to be reliable, a number of criteria should be fulfilled. These include face validity, test–retest consistency, responsiveness to reference drugs [29], and a reasonably high response rate in healthy subjects [23]. Since the clinical

**TABLE 3 Pharmacological and Nonpharmacological Models Used in PoP/PoC Trials**

| Model | Therapeutic Area |
|---|---|
| Carbon dioxide inhalation | General anxiety disorder, panic disorder |
| Conditioned aversive anxiety | Anxiety |
| Scopolamine test | Dementia/cognitive disorders |
| Pain models (mechanical, chemical, thermal or electrical stimulation) | Pain |
| Bronchial challenges (allergens, histamine, methacholine, leukotriene, cold air, UNDW) | Asthma |
| Pentagastrin-induced gastric acid secretion | Peptic ulcer, GERD |
| Human endotoxemia model | Sepsis |
| Phenylephrine challenge | Benign prostatic hyperplasia |

UNDW, Ultrasound-nebulized distilled water, GERD, gastroesophageal reflux disease.

manifestations of many diseases are multifaceted and not possible to reproduce in a model involving the administration of a single pharmacological agent, it has been suggested that the model can be useful if it provokes the cardinal symptoms of the disease [23]. Table 3 shows examples of pharmacological models that can be used in PoP/PoC trials.

### 6.2 Nonpharmacological Models

These use the same general principles as pharmacological models. However, they require rigorous standardization for reliability [23]. Examples of nonpharmacological models used in PoP/PoC paradigms include models of anxiety and panic such as simulated public speaking [30] and conditioned aversive anxiety [30], and nonpharmacological provocation tests of asthma and human experimental pain models (Table 3). The latter have evolved to provide a useful translational tool linking animal findings with data obtained in healthy subjects and patients. Moreover, by adopting a multimodal (mechanical, chemical, thermal, electrical stimuli), multitissue (skin, muscles, viscera) approach, it is now possible to explore different pain pathways and mechanisms and assess responses induced by novel putative analgesics in PoP/PoC trials. This approach is described in a recent review by Arendt-Nielsen and colleagues [31].

### 6.3 Provocation Models in Patients

PoP/PoC can also be explored using provocation models in patients. Both pharmacological and nonpharmacological models are potentially useful to progress a new compound through early clinical development. Asthma and allergic diseases are therapeutic areas where provocation models in patients are most frequently used, and the practical setup of the trials does not deviate from that in healthy volunteers. However, since the trials are conducted in the target patient population [27, 28, 32, 33], a positive outcome is more indicative of a successful PoC compared with a positive result from a provocation experiment in healthy subjects. Provocation tests for PoP/PoC in patients have also been used in other therapeutic areas, such as epilepsy. Among the models tested, the technically challenging intermittent photic stimulation in patients with photosensitive epilepsy has been found reliable in

predicting the antiseizure activity of a number of efficacious drugs that were eventually approved [34]. PoP was recently obtained for two novel antiepileptic drugs, brivaracetam, an SV2A ligand, and carisbamate, a new carbamate using this model [35, 36]. Both drugs suppressed generalized photoparoxysmal electroencephalogram (EEG) responses in treated patients. PoP studies in epilepsy using this and other models are discussed in Schmidt [37].

## 7 DIFFERENT TYPES OF POP/POC STUDIES

Considering the broad definition of PoP/PoC (see above), PoP/PoC trials are quite variable in terms of objectives, overall design, trial population, endpoints, as well as regulatory requirements.

### 7.1 Exploratory Investigational New Drug PoC Trials

These are early clinical studies conducted under the auspices of FDA's Exploratory Investigational New Drug Guidance [38], which covers microdose studies of pharmacokinetics or imaging as well as phase 0 clinical trials to study pharmacologically relevant doses. A microdose is defined as 1/100th of the dose calculated to yield a pharmacologic effect with a maximum dose of 100 μg (or 30 nmol for proteins). Imaging studies using microdoses can be very useful in establishing PoP, for example, by demonstrating significant binding of the investigational compound to the target receptor. Since these studies imply single exposures to minute amounts of the test compound, they can be conducted without the standard safety pharmacology and genotoxicity studies.

Phase 0 trials that are designed to study the pharmacologic effects of the test compounds provide a new avenue to early PoC. The FDA accepts the use of doses at which a PK/PD response or target modulation is observed in such trials. However, prerequisites are the lack of an adverse clinical response and that the dose is less than one fourth of the 2-week rodent no adverse effect level (NOAEL), or that the total exposure to drug expressed as the area under the concentration curve (AUC) does not exceed one half of the AUC at NOAEL in the most sensitive species. Due to the lower doses and consequently lower toxicity risks implied, the preclinical pharmacology and toxicology package is less extensive than that required for traditional phase I investigational new drugs (INDs), although safety pharmacology and genotoxicity studies are required. Moreover, if a "go decision" is made, based on the outcome of the study, that is, target modulation is proven, a traditional IND will have to be submitted in order to progress the compound further in clinical development.

One key therapeutic area in which phase 0 exploratory studies are performed is oncology, where there is a great need for new safe and efficacious agents and where early evidence of target modulation (molecular PoC) would potentially expedite the clinical evaluation and facilitate the development of the most promising agents. In phase 0 cancer trials, low doses are administered to a limited number of patients (10–15 patients) [39].

The most critical factor for the success of a phase 0 PoC study in oncology—and other therapeutic areas—is the availability of a sensitive, robust, and qualified/validated pharmacodynamic assay. Kinders and colleagues proposed the following

set of performance criteria for PD assay validation: accuracy, dynamic range, precision, reproducibility and sensitivity [39]. The same group reported the results of an elegant phase 0 trial [40] in which 14 patients with advanced malignancies were treated with low doses of ABT-888, a poly(ADP-ribose) polymerase inhibitor. Using a PD assay that measured the amount of the enzyme polymer in tumor tissue and blood cells as a surrogate for enzyme inhibition, the authors were able to establish the PK/PD relationship and select a dose that had a potential for efficacy with minimized risk of toxicity.

Although the exploratory IND initiative allows for a more flexible mode of developing drugs in oncology and other therapeutic areas, it remains to be seen whether phase 0 PoC studies will result in a more speedy development of safe and efficacious novel drugs.

Apart from the technical challenges that phase 0 PoC trials pose (e.g., PD assay validation), the use of patients in a trial where there is no therapeutic intent (due to subtherapeutic dosing) introduces new ethical standards in clinical research where "benefit to others" is accepted as the sole benefit. This is discussed in a thoughtful editorial [41], where phase 0 trials are described as "ethically challenged and ethically challenging."

### 7.2 Clinical Trials Using Biomarkers or Models in Healthy Subjects

These trials exploit validated or reasonably qualified "fit-for-purpose" biomarkers or models to elicit a clinically relevant pharmacological response in healthy subjects. For example, an early PoP was obtained for degarelix, a GnRH receptor antagonist currently in clinical development for prostate cancer by Ferring Pharmaceuticals, by demonstrating a rapid, profound and sustained reduction in serum levels of testosterone and LH in healthy volunteers (Figs. 3 and 4). The findings were later confirmed in large trials in the target patient population (unpublished data). The availability of a well-validated biomarker/surrogate (testosterone deprivation in prostate cancer) was crucial for the successful PoP/PoC achieved.

***FIGURE 3*** *Serum testosterone levels in healthy volunteers after the administration of degarelix intravenously, intramuscularly, and subcutaneously. The horizontal dotted line indicates the level of castration (serum testosterone of 0.5 ng/mL) required for efficacy in prostate cancer trials. Median values and quartiles are shown.*

***FIGURE 4*** *Changes (median and quartiles) in serum levels of testosterone and luteinising hormone (LH) after intravenous administration of degarelix (30μg/kg) to healthy subjects. The response confirms the mechanism of action of the compound (GnRH antagonism leading to LH decline with resultant chemical castration).*

### 7.3 Clinical Trials Using Biomarkers in Patients

In these trials, biomarkers related to the pathophysiology of the disease are analyzed and drug-induced modulation of these markers is evaluated. For truly innovative, first-in-class therapeutic agents, a biomarker-based PoP/PoC poses significant challenges. The pathophysiology of the disease is often not completely understood. Consequently, the link between the different biomarkers and the disease biology might not be evident. Therefore, a positive change in a biomarker in a patient trial may constitute a positive PoP but does not guarantee a positive clinical outcome. This is unavoidable in all cases where the biomarkers have not yet been clinically validated. However, as discussed above, the use of biomarkers in PoP/PoC trials is a way of increasing the confidence in a particular therapeutic agent or class of agents to make better internal go–no go decisions. The alternative is to rely primarily on huge clinical trials that might fail late and at a much higher cost.

One therapeutic area in which the use of biomarkers during early drug development is of particular interest is Alzheimer's disease (AD). Despite extensive R&D efforts by many large and small pharmaceutical companies, disease-modifying therapies have been elusive. The identification of presymptomatic neurodegenerative changes that are mirrored by changes in specific markers is crucial and remains to be in focus for AD research. A wide array of biochemical markers such as β-amyloid and tau proteins in CSF [42] and imaging-based biomarkers [43, 44] are available, and evidence seems to suggest that a multiple biomarker approach will be necessary [45]. The logistics of large clinical trials in AD and the fact that available symptomatic treatment of AD (cholinesterase inhibitors, memantine) influences the primary clinical endpoint (cognition), thus blurring the potential effects of a truly disease-modifying agent, make biomarker-based PoP/PoC the most attractive approach to develop such important therapies in a huge area of unmet medical need. Other proposed strategies to enhance drug development in this area include enriched population

PoC studies (patients with mild cognitive impairment who are at higher risk of developing AD), implementing alternative, more sensitive clinical outcome measurements and adaptive dose-finding trials (seamless phase IIb–III) [46].

### 7.4 Trials Using Clinical Endpoints for PoC

In the absence of qualified biomarkers or acceptable surrogates, PoC can only be established by a successful clinical trial conducted in the target patient population using solid clinical endpoints for efficacy. As discussed earlier, biomarkers that are not fully validated can still be useful in demonstrating a pharmacological effect and selecting doses for the "ultimate" PoC trial. PoC trials using clinical outcomes are usually large and can be of long duration, depending on the natural course of the disease, the drug's mode of action, and the sensitivity of the clinical measurements to therapeutic intervention.

## 8 KNOWLEDGE OF EXPOSURE–RESPONSE RELATIONSHIP OF DRUG IS ESSENTIAL FOR SUCCESSFUL POP/POC

Adequate characterization of the ER relationship of the drug is vital for robust PoP/PoC conclusions and consequently solid go–no go decisions. This is easily understood if one realizes that a primary objective of PoP/PoC trials is to demonstrate some signs of efficacy, be it direct or via a biomarker or other surrogates at a dose that does not elicit unacceptable adverse effects. Failure to explore the ER relationship properly early on carries a risk of selecting inappropriate dose(s) in the PoP/PoC trial and, consequently, making the wrong go–no go decision. Some drug developers still advocate the use of a high, tolerated dose close to the maximal tolerated dose (MTD) in a PoP/PoC trial; "if this doesn't work, why bother?" While this approach might work when developing compounds with wide therapeutic windows, it ignores the fundamental principles of clinical pharmacology and carries a significant risk of adverse drug reactions arising later in larger trials or even registering too high a dose of the drug. Finally, with increasing safety awareness, regulatory requirements often include the demonstration of the minimum dose that is maximally effective [11].

It should be underscored that a thoughtful integrated learning approach to PoP/PoC is a prerequisite for well-founded decisions. Notwithstanding the cost constraints that many pharmaceuticals companies experience, PoP/PoC strategies should not be "quick and dirty" or "lean and mean" development approaches. A rational scientifically solid and well-engineered PoP/PoC strategy indeed saves time and money by ensuring the progress of good drug candidates and the termination of compounds with poor chances of making it to the marketplace.

## 9 PROOF-OF-PRINCIPLE/PROOF-OF-CONCEPT OUTCOMES CAN BE "FALSE DAWNS"

Despite the importance of PoP/PoC trials in drug development, as underscored in the literature and reiterated in this chapter, positive trial outcomes are by no means

a guarantee of clinical success. As discussed above, PoP/PoC trials usually rely on biomarkers/surrogates/models that might not adequately predict the clinical outcome and therefore fail the ultimate test of efficacy and safety, that is, the confirmatory phase III pivotal trials. Fleming and DeMets reviewed experiences with biomarkers/surrogates that failed to predict clinical outcomes in different therapeutic areas and discussed reasons for failure [47]. These are: (a) The biomarker/surrogate is not in the causal pathway of the disease. (b) The disease involves several pathways and the drug affects only the one mediated by the biomarker. (c) The biomarker is not in the pathway affected by the drug. (d) The drug affects mechanisms that are independent of the disease process [47]. One of the most classic examples of biomarkers/surrogates failing badly in predicting serious clinical outcomes is the use of reduction of ventricular extra systoles as a surrogate for decreased cardiovascular mortality after myocardial infarction. Flecainide, encainide, and moricizine were found to increase mortality [48, 49] despite the fact that they effectively suppressed ventricular arrhythmias. All three drugs were later withdrawn from the market. This and many other sobering examples reflect the fact that conclusive answers on the efficacy and safety of drugs can only be answered by large clinical trials using solid clinical endpoints. Moreover, long-term safety evaluation often requires extensive clinical use after drug approval. However, this does not decrease the value of biomarker-based PoP/PoC as a means of demonstrating relevant pharmacological activity of new compounds and capturing early signs of potential clinical utility. After all, PoP/PoC is primarily an indication that a certain compound is reasonably good enough to develop further.

### 9.1 Summary of Selected Human Models Quoted in This Chapter that Can be Used in PoP/PoC Trials

- *Human Endotoxemia Model* This is an experimental model of sepsis using intravenously administered, purified lipopolysaccharide (LPS) from *Escherichia coli* to healthy volunteers. The endotoxin induces changes that mimic early inflammatory and cardiovascular responses in septic shock [50–54]. The model has been widely used to study the mechanisms underlying the pathophysiology of sepsis and can potentially be useful to establish early PoP/PoC for drugs targeting these mechanisms. One limitation of the model is that it may not capture the increased vascular permeability, an important feature of severe sepsis/septic shock [55, 56].
- *Carbon Dioxide Inhalation Model* Inhalation of 7.5% carbon dioxide induces anxiety manifestations in healthy subjects with a sense of fear and tension together with increases in blood pressure and heart rate [57]. This model has been shown to be sensitive to the effects of lorazepam and to some extent paroxetine [58], and might therefore be useful to establish early PoP for new compounds intended for the treatment of generalized anxiety disorder (GAD) and panic disorder.
- *Scopolamine-Induced Cognitive Impairment Model* Cognitive impairment is induced in healthy subjects using subcutaneously or intravenously administered scopolamine; and the effect of cognition enhancers can be monitored, for example, using computerized neuropsychological test battery (CNTB) and quantitative electroencephalography (qEEG) [20–22].

- *Conditioned Aversive Anxiety Model* In this model, skin conductance responses to auditory stimuli are measured. Ten neutral tones are initially presented (habituation phase), and tone 11 is immediately followed by an aversive white noise (unconditioned stimulus). The response to a second presentation of the tones (extinction phase) is recorded. Amplitude as well as spontaneous fluctuations (variability) of the skin conductance response is registered. A positive control such as diazepam is used, and compounds with putative anxiolytic effects are compared with the control [30, 59].
- *Pentagastrin-Induced Gastric Acid Secretion* In this model, maximal/submaximal gastric acid secretion is induced in healthy subjects by intravenous infusion of pentagastrin. The effect of antiulcer/GERD drugs such as proton pump inhibitors on gastric acid output and intragastric pH is measured [60, 61].
- *Phenylephrine Challenge* This model is used to investigate the effect of alpha blockers on urethral tone and blood pressure in order to estimate the selectivity for the effect on urethral smooth muscles relative to the hypotensive response [62]. Phenylephrine, which raises urethral and blood pressure, is administered by dose escalation infusions at the estimated $T_{max}$ for the compound, urethral pressure is monitored using a sensor-equipped self-retaining urethral catheter, and blood pressure is recorded simultaneously. New, more selective compounds can be tested in this model establishing PoP/PoC [62].

# BIOMARKERS ARE NOT NEW

Ian Dews, MRCP, FFPM
*Envestia Ltd., Thame, Oxfordshire, UK*

## INTRODUCTION

The word *biomarker* in its medical context is a little over 30 years old, having first been used by Karpetsky, Humphrey, and Levy in the April 1977 edition of the *Journal of the National Cancer Institute*, where they reported that the "serum RNase level … was not a biomarker either for the presence or extent of the plasma cell tumor." Few new words can have proved so popular—a recent PubMed search lists more than 370,000 publications that use it! Part of this success can no doubt be attributed to the fact that the word gave a long-overdue name to a phenomenon that has been around at least since the seventh century B.C., when Sushustra, the "father of Ayurvedic surgery," recorded that the urine of patients with diabetes attracted ants because of its sweetness. However, although the origins of biomarkers are indeed ancient, it is fair to point out that the pace of progress over the first 2500 years was somewhat less than frenetic.

## UROSCOPY

Because of its easy availability for inspection, urine was for many centuries the focus of attention. The foundation of the "science" of uroscopy is generally attributed to Hippocrates (460–355 B.C.), who hypothesized that urine was a

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

filtrate of the "humors," taken from the blood and filtered through the kidneys, a reasonably accurate description. One of his more astute observations was that bubbles on the surface of the urine (now known to be due to proteinuria) were a sign of long-term kidney disease. Galen (A.D. 129–200), the most influential of the ancient Greco-Roman physicians, sought to make uroscopy more specific but in reality added little to the subject beyond the weight of his reputation, which served to hinder further progress in this as in many other areas of medicine.

Five hundred years later, Theophilus Protospatharius, another Greek writer, moved things one step nearer to the modern world when he investigated the effects of heating urine and hence established the world's first medical laboratory test. He discovered that heating urine from patients with symptoms of kidney disease caused cloudiness (in fact, the precipitation of proteins). In the sixteenth century, Paracelsus (1493–1541) in Switzerland used vinegar to bring out the same cloudiness (acid, like heat, will precipitate proteins).

Events continued to move both farther north and closer to modernity when in 1695 Frederick Deckers of Leiden in the Netherlands identified this cloudiness as resulting from the presence of albumin. The loop was finally closed when Richard Bright (1789–1858), a physician at Guy's Hospital in London, made the connection between proteinuria and autopsy findings of abnormal kidneys.

The progress from Hippocrates' bubbles to Bright disease represents the successful side of uroscopy, but other aspects of the subject now strike us as a mixture of common sense and bizarre superstition. The technique of collecting urine was thought to be of paramount importance for accurate interpretation. In the eleventh century, Ismail of Jurjani insisted on a full 24-hour collection in a vessel that was large and clean (very sensible) and shaped like a bladder, so that the urine would not lose its "form" (not at all sensible). His advice to keep the sample out of the sun and away from heat continues, however, to be wise counsel.

Gilles de Corbeil (1165–1213), physician to King Philip Augustus of France, recorded differences in sediment and color of urine which he related to 20 different bodily conditions. He also invented the matula, or jorden, a glass vessel through which the color, consistency, and clarity of the sample could be assessed. Shaped like a bladder rounded at the bottom and made of thin clear glass, the matula was to be held up in the right (not the left) hand for careful inspection against the light. De Corbeil taught that different areas of the body were represented by the urine in different parts of the matula. These connections, which became ever more complex, were recorded on uroscopy charts that were published only in Latin, thus ensuring that the knowledge, and its well-rewarded use in treating wealthy patients, was confined to appropriately educated men. To further this education, de Corbeil, in his role as a professor at the Medical School of Salerno, set out his own ideas and those of the ancient Greek and Persian writers in a work called *Poem on the Judgment*

*of Urines*, which was set to music in order that medical students could memorize it more easily. It remained popular for several centuries.

## BLOOD PRESSURE

One of the first excursions away from urine in the search for markers of function and disease came in 1555 with the publication of a book called *Sphygmicae artis iam mille ducentos annos perditae & desideratae Libri V* by a physician from Poznán in Poland named Józef Struś (better known by his Latinized name, Iosephus Struthius). In this 366-page work, Struthius described placing increasing weights on the skin over an artery until the pulse was no longer able to lift the load. The weight needed to achieve this gave a crude measure of what he called "the strength of the pulse" or, as we would call it today, blood pressure.

Early attempts at quantitative measurement of blood pressure had to be conducted in animals rather than human subjects because of the invasiveness of the technique. The first recorded success with these techniques dates from 1733, when the Reverend Stephen Hales, a British veterinary surgeon, inserted a brass pipe into a horse's artery and connected the pipe to a glass tube. Hales observed the blood rising in the tube and concluded not only that the rise was due to the pressure of the blood in the artery but also that the height of the rise was a measure of that pressure.

By 1847, experimental technique had progressed to the point where it was feasible to measure blood pressure in humans, albeit still invasively. Carl Ludwig inserted brass cannulas directly into an artery and connected them via further brass pipework to a U-shaped manometer. An ivory float on the water in the manometer was arranged to move a quill against a rotating drum, and the instrument was known as a *kymograph* ("wave-writer" in Greek).

Meanwhile, in 1834, Jules Hérisson had described his *sphygmomètre*, which consisted of a steel cup containing mercury, covered by a thin membrane, with a calibrated glass tube projecting from it. The membrane was placed over the skin covering an artery and the pressure in the artery could be gauged from the movements of the mercury into the glass tube.

Although minor improvements were suggested by a number of authors over the next few years, credit for the invention of the true *sphygmomanometer* goes to Samuel Siegfried Karl Ritter von Basch, whose original 1881 model used water in both the cuff and the manometer tube. Five years later, Scipione Riva-Rocci introduced an improved version in which an inflatable bag in the cuff was connected to a mercury manometer, but neither of these early machines attracted widespread interest. Only in 1901, when the famous American surgeon Harvey Cushing brought back one of Riva-Rocci's machines on his return from a trip to Italy, did noninvasive blood pressure measurement really take off.

Sphygmomanometers of the late nineteenth century relied on palpation of the pulse and so could only be used to determine systolic blood pressure. Measurement of diastolic pressure only became possible when Nikolai Korotkoff observed in 1905 that characteristic sounds were made by the constriction of the artery at certain points in the inflation and deflation of the cuff. The greater accuracy allowed by auscultation of these *Korotkoff sounds* opened the way for the massive expansion in blood pressure research that characterized the twentieth century.

## IMAGING

To physicians keen to understand the hidden secrets of the human body, few ideas can have been more appealing than the dream of looking through the skin to examine the tissues beneath. The means for achieving this did not appear until a little over a century ago, and then very much by accident. On the evening of November 8, 1895, Wilhem Roentgen, a German physicist working at the University of Würzburg, noticed that light was coming from fluorescent material in his laboratory and worked out that this was the result of radiation escaping from a shielded gas discharge tube with which he was working. He was fascinated by the ability of this radiation to pass through apparently opaque materials and promptly set about investigating its properties in more detail. While conducting experiments with different thicknesses of tinfoil, he noticed that that if the rays passed though his hand, they cast a shadow of the bones.

Quick to see the potential medical uses for his new discovery, Roentgen immediately wrote a paper entitled "On a new kind of ray: a preliminary communication" for the Würzburg Physical Medical Society, reprints of which he sent to a number of eminent scientists with whom he was friendly. One of these, Franz Exner of Vienna, was the son of the editor of the *Vienna Presse*, and hence the news was published quickly, first in that paper and then across Europe. Whereas we are inclined to believe that rapid publication is a feature of the Internet age, the Victorians were no slouches in this matter, and by January 24, 1896 a reprint of the Würzburg paper had appeared in the London *Electrician*, a major journal able to bring details of the new invention to a much wider technical audience.

The speed of the response was remarkable. Many physics laboratories already had gas discharge tubes, and within a month physicists in a dozen countries were reproducing Roentgen's findings. Edwin Frost produced an x-ray image of a patient's fractured wrist for his physician brother, Gilmon Frost, at Dartmouth College in the United States, while at McGill University in Montreal, John Cox used the new rays to locate a bullet in a gunshot victim's leg. Similar results were obtained in cities as far apart as Copenhagen, Prague, and Rijeka in Croatia. Inevitably, not everyone was initially quite so impressed; *The Lancet* of February 1, 1896 expressed considerable surprise that the

Belgians had decided to bring x-rays into practical use in hospitals throughout the country! Nevertheless, it was soon clear that a major new diagnostic tool had been presented to the medical world, and there was little surprise when Roentgen received a Nobel Prize in Physics in 1901.

Meanwhile, in March 1896, Henri Becquerel, professor of physics at the Muséum National d'Histoire Naturelle in Paris, while investigating Roentgen's work, wrapped a fluorescent mineral, potassium uranyl sulfate, in photographic plates and black material in preparation for an experiment requiring bright sunlight. However, a period of dull weather intervened, and prior to actually performing the experiment, Becquerel found that the photographic plates were fully exposed. This led him to write: "One must conclude from these experiments that the phosphorescent substance in question emits rays which pass through the opaque paper and reduce silver salts." Becquerel received a Nobel prize, which he shared with Marie and Pierre Curie, in 1903, but it was to be many years before the use of spontaneous radioactivity reached maturity in medical investigation in such applications as isotope scanning and radioimmunoassay.

The use of a fluoroscopic screen on which to view x-ray pictures was implicit in Roentgen's original discovery and soon became part of the routine equipment not only of hospitals but even of shoe shops, where large numbers of children's shoe fittings were carried out in the days before the true dangers of radiation were appreciated. However, the greatest value of the real-time viewing approach only emerged following the introduction of electronic image intensifiers by the Philips company in 1955.

Within months of the introduction of planar x-rays, physicians were asking for a technique that would demonstrate the body in three dimensions. This challenge was taken up by a number of scientists in different countries, but because of the deeply ingrained habit of reviewing only the national, not the international, literature, these workers remained ignorant of each other's progress for many years.

Carl Mayer, a Polish physician, first suggested the idea of tomography in 1914. André-Edmund-Marie Bocage in France, Gustav Grossmann in Germany, and Allesandro Vallebona in Italy all developed the idea further and built their own equipment. George Ziedses des Plantes in the Netherlands pulled all these strands together in the 1930s and is generally considered the founder of conventional tomography.

Further progress had to wait for the development of powerful computers, and it was not until 1972 that Godfrey Hounsfield, an engineer at EMI, designed the first computer-assisted tomographic device, the EMI scanner, installed at Atkinson Morley Hospital, London, an achievement for which he received both a Nobel prize and a knighthood.

Parallel with these advances in x-ray imaging were ongoing attempts to make similar use of the spontaneous radioactivity discovered by Becquerel. In 1925, Herrman Blumgart and Otto Yens made the first use of radioactivity as a biomarker when they used bismuth-214 to determine the arm-to-arm

circulation time in patients. Sodium-24, the first artificially created biomarker radioisotope, was used by Joseph Hamilton to investigate electrolyte metabolism in 1937.

Unlike x-rays, however, radiation from isotopes weak enough to be safe was not powerful enough to create an image merely by letting it fall on a photographic plate. This problem was solved when Hal Anger of the University of California, building on the efficient gamma-ray capture system using large flat crystals of sodium iodide doped with thallium developed by Robert Hofstadter in 1948, constructed the first gamma camera in 1957.

The desire for three-dimensional images that led to tomography with x-rays also influenced radioisotope imaging and drove the development of single-photon-emission computed tomography (SPECT) by David Kuhl and Roy Edwards in 1968. Positron-emission tomography (PET) also builds images by detecting energy given off by decaying radioactive isotopes in the form of positrons that collide with electrons and produce gamma rays that shoot off in nearly opposite directions. The collisions can be located in space by interpreting the paths of the gamma rays, and this information is then converted into a three-dimensional image slice. The first PET camera for human studies was built by Edward Hoffman, Michael Ter-Pogossian, and Michael Phelps in 1973 at Washington University. The first whole-body PET scanner appeared in 1977.

Radiation, whether from x-ray tubes or from radioisotopes, came to be recognized as having dangers both for the patient and for personnel operating the equipment, and efforts were made to discover media that would produce images without these dangers. In the late 1940s, George Ludwig, a junior lieutenant at the Naval Medical Research Institute in Bethseda, Maryland, undertook experiments using industrial ultrasonic flaw-detection equipment in an attempt to determine the acoustic impedance of various tissues, including human gallstones surgically implanted into the gallbladders of dogs. His observations were detailed in a 30-page project report to the Naval Medical Research Institute dated June 16, 1949, now considered the first report of its kind on the diagnostic use of ultrasound. However, a substantial portion of Ludwig's work was considered classified information by the Navy and was not published in medical journals.

Civilian research into what became the two biggest areas of early ultrasonic diagnosis—cardiology and obstetrics—began in Sweden and Scotland, respectively, both making use of gadgetry initially designed for shipbuilding. In 1953, Inge Edler, a cardiologist at Lund University collaborated with Carl Hellmuth Hertz, a graduate student in the department of nuclear physics who was familiar with using ultrasonic reflectoscopes for nondestructive materials testing, and together they developed the idea of using this method in medicine. They made the first successful measurement of heart activity on October 29, 1953 using a device borrowed from Kockums, a Malmö shipyard. On December 16 of the same year, the method was used to generate an echo encephalogram. Edler and Hertz published their findings in 1954.

At around the same time, Ian Donald of the Glasgow Royal Maternity Hospital struck up a relationship with boilermakers Babcock & Wilcox in Renfrew, where he used their industrial ultrasound equipment to conduct experiments assessing the ultrasonic characteristics of various in vitro preparations. With fellow obstetrician John MacVicar and medical physicist Tom Brown, Donald refined the equipment to the point where it could be used successfully on live volunteer patients. These findings were reported in *The Lancet* on June 7, 1958 as "Investigation of abdominal masses by pulsed ultrasound."

Nuclear magnetic resonance (NMR) in molecules was first described by Isidor Rabi in 1938. His work was followed up eight years later by Felix Bloch and Edward Mills Purcell, who, working independently, noticed that magnetic nuclei such as hydrogen and phosphorus, when placed in a magnetic field of a specific strength, absorb radio-frequency energy, a situation described as being "in resonance."

For the next 20 years NMR found purely physical applications in chemistry and physics, and it was not until 1971 that Raymond Damadian showed that the nuclear magnetic relaxation times of different tissues, especially tumors, differed, thus raising the possibility of using the technique to detect disease. Magnetic resonance imaging (MRI) was first demonstrated on small test tube samples in 1973 by Paul Lauterbur, and in 1975 Richard Ernst proposed using phase and frequency encoding and the Fourier transform, the technique that still forms the basis of MRI.

The first commercial nuclear magnetic imaging scanner allowing imaging of the body appeared in 1980 using Ernst's technique, which allowed a single image to be acquired in approximately 5 minutes. By 1986, the imaging time was reduced to about 5 seconds without sacrificing too much image quality. In the same year, the NMR microscope was developed, which allowed approximately 10-mm resolution on approximately 1-cm samples. In 1993, functional MRI (fMRI) was developed, thus permitting the mapping of function in various regions of the brain.

## ELECTROCARDIOGRAPHY

Roentgen's discovery of x-rays grew out of the detailed investigation of electricity that was a core scientific concern of the nineteenth century, and it is little surprise that investigators also took a keen interests in the electricity generated by the human body itself. Foremost among these was Willem Einthoven. Before his day, although it was known that the body produced electrical currents, the technology was inadequate to measure or record them with any sort of accuracy. Starting in 1901, Einthoven, a professor at the University of Leiden, conducted a series of experiments using a string galvanometer. In his device, electric currents picked up from electrodes on the patient's skin passed through a thin filament running between very

strong electromagnets. The interaction of the electric and magnetic fields caused the filament or "string" to move, and this was detected by using a light to cast a shadow of the moving string onto a moving roll of photographic paper.

It was not, at first, an easy technique. The apparatus weighed 600 lb, including the water circulation system essential for cooling the electromagnets, and was operated by a team of five technicians. Over the next two decades Einthoven gradually refined his machine and used it to establish the electrocardiographic (ECG) features of many different heart conditions, work that was eventually recognized with a Nobel prize in 1924.

As the ECG became a routine part of medical investigations it was realized that a system that gave only a "snapshot" of a few seconds of the heart's activity could be unhelpful or even misleading in the investigation of intermittent conditions such as arrhythmias. This problem was addressed by Norman Holter, an American biophysicist, who created his first suitcase-sized "ambulatory" monitor as early as 1949, but whose technique is dated in many sources to the major paper that he published on the subject in 1957, and other authors cite an even later, 1961 publication.

## HEMATOLOGY

The scientific examination of blood in order to learn more about the health of the patient from whom it was taken can be dated to 1642, when Anthony van Leeuwenhoek first observed blood cells through his newly invented microscope. Progress was at first slow, and it was not until 1770 that leucocytes were discovered by William Hewson, an English surgeon, who also observed that red cells were flat rather than spherical, as had earlier been supposed.

Association of blood cell counts with clinical illness depended on the development of a technical method by which blood cells could be counted. In 1852, Karl Vierordt at the University of Tübingen developed such a technique, which, although too tedious for routine use, was used by one of his students, H. Welcher, to count red blood cells in a patient with "chlorosis" (an old word for what is probably our modern iron-deficiency anemia). He found, in 1854, that an anemic patient had significantly fewer red blood cells than did a normal person. Platelets, the third major cellular constituent of blood, were identified in 1862 by a German anatomist, Max Schultze.

Remarkably, all these discoveries were made without the benefit of cell staining, an aid to microscopic visualization that was not introduced until 1877 in Paul Ehrlich's doctoral dissertation at the University of Leipzig. The movement of blood cell studies from the research laboratory to routine support of patient care needed a fast automatic technique for separating and counting cells, which was eventually provided by the Coulter brothers, Wallace and Joseph. In 1953 they patented a machine that detected the change in electrical conductance of a small aperture as fluid containing cells was drawn through.

Cells, being nonconducting particles, alter the effective cross section of the conductive channel and so signal both their presence and their size.

An alternative technique, flow cytometry, was also developed in stages between the late 1940s and the early 1970s. Frank Gucker at Northwestern University developed a machine for counting bacteria in a laminar stream of air during World War II and used it to test gas masks, the work subsequently being declassified and published in 1947. Louis Kamentsky at IBM Laboratories and Mack Fulwyler at the Los Alamos National Laboratory experimented with fluidic switching and electrostatic cell detectors, respectively, and both described cell sorters in 1965. The modern approach of detecting cells stained with fluorescent antibodies was developed in 1972 by Leonard Herzenberg and his team at Stanford University, who coined the term *fluorescence-activated cell sorter* (FACS).

## BLOOD AND URINE CHEMISTRY

As with hematology, real progress in measuring the chemical constituents of plasma depended largely on the development of the necessary technology. Until such techniques became available, however, ingenious use was made of bioassays, developed in living organisms or preparations made from them, to detect and in some cases quantify complex molecules. A good example of this is the detection of human chorionic gonadotrophin (hCG) in urine as a test for pregnancy. Selmar Aschheim and Bernhard Zondek in Berlin, who first isolated this hormone in 1928, went on to devise the Aschheim–Zondek pregnancy test, which involved five days of injecting urine from the patient repeatedly into an infantile female mouse which was subsequently killed and dissected. The finding of ovulation in the mouse indicated that the injected urine contained hCG and meant that the patient was pregnant.

In the early 1940s, the mouse test gave way to the frog test, introduced by Lancelot Hogben in England. This was a considerable improvement, in that injection of urine or serum from a pregnant woman into the dorsal lymph sac of the female African clawed frog (*Xenopus laevis*) resulted in ovulation within 4 to 12 hours. Although this test was known to give a relatively high proportion of false negatives, it was regarded as an outstanding step forward in diagnosis. One story from the 1950s recounts that with regard to the possible pregnancy of a particular patient, "opinions were sought from an experienced general practitioner, an eminent gynecologist, and a frog; only the frog proved to be correct."

Pregnancy testing, and many other "biomarker" activities, subsequently moved from out-and-out bioassays to the "halfway house" of immunological tests based on antibodies to the test compound generated in a convenient species but then used in an ex vivo laboratory setting, and in 1960 a hemagglutination inhibition test for pregnancy was developed by Leif Wide and Carl Gemzell in Uppsala.

Not all immune reactions can be made to modulate hemagglutination, and a problem with the development of immunoassays was finding a simple way to detect whether the relevant antibody or antigen was present. One answer lay in the use of radiolabeled reagents. Radioimmunoassay was first described in a paper by Rosalyn Sussman Yalow and Solomon Berson published in 1960.

Radioactivity is difficult to work with because of its safety concerns, so an alternative was sought. This came with the recognition that certain enzymes (such as ABTS or 3,3′,5,5′-tetramethylbenzidine) which react with appropriate substrates to give a color change could be linked to an appropriate antibody. This linking process was developed independently by Stratis Avrameas and G. B. Pierce. Since it is necessary to remove any unbound antibody or antigen by washing, the antibody or antigen must be fixed to the surface of the container, a technique first published by Wide and Porath in 1966.

In 1971, Peter Perlmann and Eva Engvall at Stockholm University, as well as Anton Schuurs and Bauke van Weemen in the Netherlands, independently published papers that synthesized this knowledge into methods to perform enzyme-linked immunosorbent assay (ELISA).

A further step toward physical methods was the development of chromatography. The word was coined in 1903 by the Russian botanist Mikhail Tswett to describe his use of a liquid–solid form of a technique to isolate various plant pigments. His work was not widely accepted at first, partly because it was published in Russian and partly because Arthur Stoll and Richard Willstätter, a much better known Swiss–German research team, were unable to repeat the findings.

However, in the late 1930s and early 1940s, Archer Martin and Richard Synge at the Wool Industries Research Association in Leeds devised a form of liquid–liquid chromatography by supporting the stationary phase, in this case water, on silica gel in the form of a packed bed and used it to separate some acetyl amino acids derived from wool. Their 1941 paper included a recommendation that the liquid mobile phase be replaced with a suitable gas that would accelerate the transfer between the two phases and provide more efficient separation: the first mention of the concept of gas chromatography. In fact, their insight went even further, in that they also suggested the use of small particles and high pressures to improve the separation, the starting point for high-performance liquid chromatography (HPLC).

Gas chromatography was the first of these concepts to be taken forward. Erika Cremer working with Fritz Prior in Germany developed gas–solid chromatography, while in the UK, Martin himself cooperated with Anthony James in the early work on gas–liquid chromatography published in 1952. Real progress in HPLC began in 1966 with the work of Csaba Horváth at Yale. The popularity of the technique grew rapidly through the 1970s, so that by 1980, this had become the standard laboratory approach to a wide range of analytes. The continuing problem with liquid or gas chromatography was the identification of the molecule eluting from the system, a facet of the techniques that was to be revolutionized by mass spectrometry.

The foundations of mass spectrometry were laid in the Cavendish Laboratories of Cambridge University in the early years of the twentieth century. Francis Aston built the first fully functional mass spectrometer in 1919 using electrostatic and magnetic fields to separate isotope ions by their masses and focus them onto a photographic plate. By the end of the 1930s, mass spectrometry had become an established technique for the separation of atomic ions by mass.

The early 1950s saw attempts to apply the technique to small organic molecules, but the mass spectrometers of that era were extremely limited by mass and resolution. Positive theoretical steps were taken, however, with the description of time-of-flight (TOF) analysis by W. C. Wiley and I. H. Maclaren. and quadruple analysis by Wolfgang Pauli.

The next major development was the coupling of gas chromatography to mass spectrometry in 1959 by Roland Gohlke and Fred McLafferty at the Dow Chemical Research Laboratory in Midland, Michigan. This allowed, for the first time, an analysis of mixtures of analytes without laborious separation by hand. This, in turn, was the trigger for the development of modern mass spectrometry of biological molecules.

The introduction of liquid chromatography–mass spectrometry (LC-MS) in the early 1970s, together with new ionization techniques developed over the last 25 years (i.e., fast particle desorption, electrospray ionization, and matrix-assisted laser desorption/ionzation), have made it possible to analyze almost every class of biological compound class right up into the megadalton range.

## FASHIONABLE "OMICS"

In Benet Street, Cambridge, stands a rather ordinary pub which on Saturday, February 28, 1953, enjoyed 15 minutes of fame far beyond Andy Warhol's wildest dreams. Two young men arrived for lunch and, as James Watson watched, Francis Crick announced to the regulars in the bar that "we have found the secret of life." The more formal announcement of the structure of DNA appeared in *Nature* on April 2 in a commendably brief paper of two pages with six references. Watson and Crick shared a Nobel prize with Maurice Wilkins, whose work with Rosalind Franklin at King's College, London had laid the groundwork. Sadly, Franklin's early death robbed her of a share of the prize, which is never awarded posthumously.

Over the next two decades a large number of researchers teased out the details of the genetic control of cells, and by 1972 a team at the Laboratory of Molecular Biology of the University of Ghent, led by Walter Fiers, were the first to determine the sequence of a gene (a coat protein from a bacteriophage). The same team followed up in 1976 by publishing the complete RNA nucleotide sequence of the bacteriophage. The first DNA-based genome to be sequenced in its entirety was the 5368-base-pair sequence of bacteriophage

Φ-X174 elucidated by Frederick Sanger in 1977. The science of genomics had been born.

Although the rush to sequence the genomes of ever more complex species (including humans in 2001) initially held out considerable hope of yielding new biomarkers, focus gradually shifted to the protein products of the genes. This process is dated by many to the introduction in 1977 by Patrick O'Farrell at the University of Colorado in Boulder of two-dimensional polyacrylamide gel electrophoresis (2-D PAGE). The subject really took off in the 1990s, however, with technical improvements in mass spectrometers combined with computing hardware and software to support the extremely complex analyses involved.

The next "omics" to become fashionable was metabolomics, based on the realization that the quantitative and qualitative pattern of metabolites in body fluids reflects the functional status of an organism. The concept is by no means new, the first paper addressing the idea (but not using the word) having been "Quantitative Analysis of Urine Vapor and Breath by Gas–Liquid Partition Chromatography" by Robinson and Pauling in 1971. The word *metabolomics*, however, was not coined until the 1990s.

## THE FUTURE

Two generalizations may perhaps be drawn from the accelerating history of biomarkers over the last 2700 years. The first is that each new step depends on an interaction between increasing understanding of the biology and technical improvement of the tools leading to a continuous spiral of innovation. The second is the need for an open but cautious mind. Sushustra's recognition of the implications of sweet urine has stood the test of time; de Corbeil's *Poem on the Judgment of Urines* has not. The ultimate fate of more recent biomarkers will only be revealed by time.

# BIOMARKERS: FACING THE CHALLENGES AT THE CROSSROADS OF RESEARCH AND HEALTH CARE

Gregory J. Downing, D.O., Ph.D.
*U.S. Department of Health and Human Services, Washington, DC*

## INTRODUCTION

Across many segments of the biomedical research enterprise and the health care delivery sectors, the impact of biomarkers has been transforming in many ways: from business and economics to policy and planning of disease management. The pace of basic discovery research progress has been profound worldwide, with the intertwining of innovative technologies and knowledge providing extensive and comprehensive lists of biological factors now known to play integral roles in disease pathways. These discoveries have had a vast impact on pharmaceutical and biotechnology industries, with tremendous growth in investment in biomarker research reaching into the laboratory technology and services sector. These investments have spawned new biomedical industry sectors, boosted the roles of contract research organizations, supported vast new biomarker discovery programs in large corporate organizations, and prompted the emergence of information management in research. Similarly, growth in the academic research programs supporting biomarker research has greatly expanded training capacity, bench and clinical research capacity, and infrastructure, while fueling the growth of intellectual property.

By many reports, private-sector applications of biomarkers in toxicity and early efficacy trials have been fruitful in developing decision-making priorities that are introducing greater efficiency in early to midstage medical product development. Despite the heavy emphasis in private and publicly funded research, the reach of the impact of biomarkers into clinical practice interventions at present is challenging to quantify. The costs of development remain high for many drugs, and the numbers of new chemical entities reaching the marketplace have continued to remain relatively low compared to prior years and expectations following robust research expansion of the 1980s and 1990s. Industry concerns about the sustainability of research and development programs have grown in the backdrop of the clinical challenges that are attendant on biomarker applications in clinical trials. Understanding of the clinical implications of disease markers as a consequence of relatively slow evidence development has taken much longer to discern than many had predicted. There have been many challenges in establishing a translational research infrastructure that serves to verify and validate the clinical value of biomarkers as disease endpoints and their value as independent measures of health conditions. The lack of the equivalent of the clinical trial infrastructure for biomarker validation and diagnostics has slowed progress compared to therapeutic and device development. Evidence development processes and evaluations have only now begun to emerge for biomarkers, and wide adoption of them in clinical practice measures has not yet matured. For some, the enthusiasm and economic balance sheets have not been squared, as the clinical measure indices that had been hoped for have been viewed as moderately successful by some and by others as bottlenecks in the pipelines of therapeutic and diagnostic development.

## BRIEF HISTORY OF BIOMARKER RESEARCH, 1998–2008: THE FIRST DECADE

During the last decade of the twentieth century, biomedical research underwent one of the most dramatic periods of change in history. Influenced by a multitude of factors—some scientific, others economic, and still others of policy—new frontiers of science emerged as technology and knowledge converged, and diverged—bringing new discoveries and hope to the forefront of medicine and health. These capabilities came about as a generation's worth of science that brought to the mainstream of biomedical research the foundation for a molecular basis of disease: recombinant DNA technology. Innovative applications of lasers, novel medical imaging platforms, and other advanced technologies began to yield a remarkable body of knowledge that provided unheralded opportunities for discovery of new approaches to the management of human health and disease.

Here we briefly revisit a part of the medical research history that led to the shaping of new directions that is, for now, captured simply by the term

*biomarker*, a biological indicator of health or disease. In looking backward to the 1980s and 1990s and the larger scheme of health care, many new challenges were being faced. The international challenges and global economic threats posed by human immunodeficiency virus (HIV) and AIDS provided the impetus for one of the first steps in target-designed therapies and the use of viral and immune indicators of disease. For the first time, strategically directed efforts in discovery and clinical research paradigms were coordinated at the international level using clinical measures of disease at the molecular level. The first impact of biomarkers on discovery and translational research, both privately and publicly funded, as related to biological measures of viral load, CD4+ T-lymphocyte counts, and other parameters of immune function and viral resistance came to be a mainstay in research and development. Regulatory authority was put in place to allow "accelerated approval" of medical products using surrogate endpoints for health conditions with grave mortality and morbidity. Simultaneously, clinical cancer therapeutics programs had some initial advances with the use of clinical laboratory tests that aided in the distinction between responders and nonresponders to targeted therapies. The relation of *Her2/neu* tyrosine kinase receptor in aggressive breast cancer and response to (Herceptin) [1], and similarly, the association of imatinib (Gleevac) responsiveness with the association of the presence of Philadelphia chromosome translocation involving *BCR/Abl* genes in chronic myelogenous leukemia [2], represented some of the cases where targeted molecular therapies were based on a biomarker test as a surrogate endpoint for patient clinical response. These represented the entry point of pharmaceutical science moving toward co-development, using diagnostic tests to guide selection of therapy around a biomarker.

Diverse changes were occurring throughout the health care innovation pipeline in the 1990s. The rise of the biotechnology industry became an economic success story underpinned by successful products in recombinant DNA technology, monoclonal antibody production, and vaccines. The device manufacturing and commercial laboratory industries became major forces. In the United States, the health care delivery system underwent changes with the widespread adoption of managed care programs, and an effort at health care reform failed. For U.S.-based academic research institutions, it was a time of particular tumult for clinical research programs, often supported through clinical care finances, downsized in response to financial shortfalls. At a time when scientific opportunity in biomedicine was, arguably, reaching its zenith, there were cracks in the enterprise that was responsible for advancing basic biomedical discovery research to the clinic and marketplace.

In late 1997, the director of the National Institutes of Health, Harold Varmus, met with biomedical research leaders from academic, industrial, governmental, and clinical research organizations, technology developers, and public advocacy groups to discuss mutual challenges, opportunities, and responsibilities in clinical research. In this setting, some of the first strategic considerations regarding "clinical markers" began to emerge among stake-

holders in clinical research. From a science policy perspective, steps were taken to explore and organize information that brought to light the need for new paradigms in clinical development. Some of these efforts led to the framing of definitions of terms to be used in clinical development, such as *biomarkers* (a characteristic that is measured and evaluated objectively as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention) and *surrogate endpoints* (a biomarker that is intended to substitute for a clinical endpoint and is expected to predict clinical benefit or harm, or lack of benefit or harm, based on epidemiologic, therapeutic, pathophysiologic, or other scientific evidence) and descriptions of the information needs and strategic and tactical approaches needed to apply them in clinical development [3]. A workshop was held to address statistical analysis, methodology, and research design issues in bridging empirical and mechanism-based knowledge in evaluating potential surrogate endpoints [4]. In-depth analyses were held to examine information needs, clinical training skills, database issues, regulatory policies, technology applications, and candidate disease conditions and clinical trials that were suitable for exploring biomarker research programs. As a confluence of these organizational activities, in April 1999 an international conference was hosted by the National Institutes of Health (NIH) and U.S. Food and Drug Administration (FDA) [5]. The leadership focused on innovations in technology applications, such as multiplexed gene analysis using polymerase chain reaction technologies, large-scale gel analysis of proteins, and positron-emission tomography (PET) and magnetic resonance imaging (MRI). A summary analysis was crafted for all candidate markers for a wide variety of disease states, and a framework was formed for multiple disease-based public–private partnerships in biomarker development. A series of research initiatives supported by industry, NIH, and FDA were planned and executed in ensuring months. New infrastructure for discovery and validation of cancer biomarkers was put in place. Public–private partnerships for biomarker discovery and characterization were initiated in osteoarthritis, Alzheimer disease, and multiple sclerosis. Research activities in toxicology markers for cardiovascular disease and metabolism by renal and hepatic transformation systems were initiated by FDA. These events did not yield a cross-sector strategic action plan, but did serve as a framework for further engagement across governmental, academic, industrial, and nongovernmental organizations. Among the breakthroughs was the recognition that new statistical analysis methods and clinical research designs would be needed to address multiple variables measured simultaneously and to conduct metaanalyses from various clinical studies to comprehend the effects of a biomarker over time and its role as a reliable surrogate endpoint. Further, it was recognized that there would be needs for data management, informatics, clinical registries, and repositories of biological specimens, imaging files, and common reagents.

Over the next several years, swift movement across the research and development enterprise was under way. It is obvious that future biomarker research

**TABLE 1 Major Scientific Contributions and Research Infrastructure Supporting Biomarker Discovery**

was driven in the 1990s and early years of the twenty-first century by the rapid pace of genome mapping and the fall in cost of large-scale genomic sequencing technology, driven by the Human Genome Project. A decade later, it is now apparent that biomarker research in the realm of clinical application has acquired a momentum of its own and is self-sustaining.

The major schemes for applications of biomarkers can be described in a generalized fashion in four areas: (1) molecular target discovery, (2) early-phase drug development, (3) clinical trials and late-stage therapeutic development, and (4) clinical applications for health status and disease monitoring. The building blocks for biomarker discovery and early-stage validation over the last decade are reflected in Table 1. Notable to completion of the international Human Genome Project was the vast investment in technology, database development, training, and infrastructure that have been applied throughout industry toward clinical research applications.

## SCIENCE AND TECHNOLOGY ADVANCES IN BIOMARKER RESEARCH

In the past decade of biomarker research, far and away the most influential driving force was completion of the Human Genome Project in 2003. The impact of this project on biomarker research has many facets beyond establishment of the reference data for human DNA sequences. This mammoth undertaking initiated in 1990 led to the sequence for the nearly 25,000 human genes and to making them accessible for further biological study. Beyond this and the other species genomes that have been characterized,

human initiatives to define individual differences in the genome provided some of the earliest large-scale biomarker discovery efforts. The human haplotype map (HapMap) project defined differences in single-nucleotide polymorphisms (SNPs) in various populations around the world to provide insights into the genetic basis of disease and into genes that have relevance for individual differences in health outcomes. A collaboration among 10 pharmaceutical industry companies and the Wellcome Trust Foundation, known as the SNP consortium, was formed in 1999 to produce a public resource of SNPs in the human genome [6]. The SNP consortium used DNA resources from a pool of samples obtained from 24 people representing several racial groups. The initial goal was to discover 300,000 SNPs in two years, but the final results exceeded this, as 1.8 million SNPs had been released into the public domain at the end of 2002 when the discovery phase was completed. The SNP consortium was notable, as it would serve as a foundation for further cross-industry public–private partnerships that would be spawned as a wide variety of community-based efforts to hasten the discovery of genomic biomarkers (see below).

The next phase of establishing the basic infrastructure to support biomarker discovery, particularly for common chronic diseases, came in 2002 through the International HapMap Project, a collaboration among scientists and funding agencies from Japan, the United Kingdom, Canada, China, Nigeria, and the United States [7]. A haplotype is a set of SNPs on a single chromatid that are associated statistically. This rich resource not only mapped over 3.1 million SNPs, but established additional capacity for identifying specific gene markers in chronic diseases and represented a critical reference set for enabling population-based genomic studies to be done that could establish a gene–environmental basis for many diseases [8].

Within a short time of completing the description of the human genome, a substantial information base was in place to enable disease–gene discoveries on a larger scale. This approach to referencing populations to the well-described SNP maps is now the major undertaking for defining gene-based biomarkers. In recent years, research groups around the world have rapidly been establishing genome-wide association studies to identify specific gene sets associated with diseases for a wide range of chronic diseases.

This new era in population-based genetics began with a small-scale study that led to the finding that age-related macular degeneration is associated with a variation in the gene for complement factor H, which produces a protein that regulates inflammation [9]. The first major implication in a common disease was revealed in 2007 through a study of type II diabetes variants [10]. To demonstrate the rapid pace of discovery of disease gene variants: At the time of this writing, within 18 months following the study, there are now 18 disease gene variants associated with defects in insulin secretion [11].

The rapid growth in genome-wide association studies (GWASs) is identifying a large number of multigene variants that are leading to subclassification

of diseases with common phenotype presentations. Among the databases being established for enabling researchers public access to these association studies is dbGaP, the database of genotype and phenotype. The database, which was developed and is operated by the National Library of Medicine's National Center for Biotechnology Information, archives and distributes data from studies that have investigated the relationship between phenotype and genotype, such as GWASs. At present, dbGAP contains 36 population-based studies that include genotype and phenotype information. Worldwide, dozens if not hundreds of GWASs are under way for a plethora of health and disease conditions associated with genetic features. Many of these projects are collaborative, involve many countries, and are supported through public–private partnerships. An example is the Genomics Association Information Network (GAIN), which is making genotype–phenotype information publicly available for a variety of studies in mental health disorders, psoriasis, and diabetic nephropathy [12]. For the foreseeable future, substantial large-scale efforts will continue to characterize disease states and catalog genes associated with clinically manifested diseases.

As technology and information structures advance, other parameters of genetic modifications represent new biomarker discovery opportunities. The use of metabolomics, proteomics, and epigenomics in clinical and translational research is now being actively engaged. A new large-scale project to sequence human cancers, the Cancer Genome Atlas, is focused on applying large-scale biology in the hunt for new tumor genes, drug targets, and regulatory pathways. This project is focused not only on polymorphisms but also on DNA methylation patterns and copy numbers as biomarker parameters [13]. Again, technological advances are providing scientists with novel approaches to inferring sites of DNA methylation at nucleotide-level resolution using a technique known as high-throughput bisulfite sequencing (HTBS). Large-scale initiatives are also under way to bring a structured approach to relating protein biomarkers into focus for disease conditions. Advances in mass spectrometry, protein structure resolution, bioinformatics for archiving protein-based information, and worldwide teams devoted to disease proteomes have solidified in recent years. Although at a more nascent stage of progress in disease characterization, each of these emerging new fields is playing a key complementary role in biomarker discovery in genetics and genomics.

Supporting this growth in biomarker discovery is massive investment over the last 10 years worldwide by public and private financers that has spawned hundreds of new commercial entities worldwide. Private-sector financing for biomarker discovery and financing has become a major component of biomedical research and development (R&D) costs in pharmaceutical development. Although detailed budget summaries have not been established for U.S. federal funding of biomarker research, in a recent survey by McKinsey and Co., biomarker R&D expenditures in 2009 were estimated at $5.3 billion, up from $2.2 billion in 2003 [14].

## POLICIES AND PARTNERSHIPS

Although progress in biomarker R&D has accelerated, the clinical translation of disease biomarkers as endpoints in disease management and as the foundation for diagnostic products has had more extensive challenges. A broad array of international policy matters over the past decade have moved to facilitate biomarker discovery and validation (Table 2). In the United States, the FDA has taken a series of actions to facilitate applications of biomarkers in drug development and use in clinical practices as diagnostic and therapeutic monitoring. A voluntary submission process of genomic data from therapeutic development was initiated by the pharmaceutical industry and the FDA in 2002 [15]. This program has yielded many insights into the role of drug-metabolizing enzymes in the clinical pharmacodynamic parameters of biomarkers in drug development. In July 2007, guidelines for the use of multiplexed genetic tests in clinical practice to monitor drug therapy were issued by the FDA [16] More recently, the FDA has begun providing label requirements indicating those therapeutic agents for which biomarker assessment can be recommended to avoid toxicity and enhance the achievement of therapeutic responses [17]. In 2007, Congress authorized the establishment of a private–public resource to support collaborative research with the FDA.

One of the major obstacles to clinical genomic research expressed over the years has been a concern that research participants may be discriminated against in employment and provision of health insurance benefits as a result of the association of genetic disease markers. After many years of deliberation, the U.S. Congress passed legislation known as the Genetic Information Non-discrimination Act of 2008, preventing the use of genetic information to deny employment and health insurance.

The past decade has seen many new cross-organizational collaborations and organizations developed to support biomarker development. For example, the

**TABLE 2 Major International Policy Issues Related to Biomarker Research**

| |

| Genetic Information Non-discrimination Act of 2008 (U.S.) |

American Society for Clinical Oncology, the American Association for Cancer Research, and the FDA established collaborations in workshops and research discussions regarding the use of biomarkers for ovarian cancer as surrogate endpoints in clinical trials [18]. The FDA Critical Path Initiative was developed in 2006, with many opportunities described for advancing biomarkers and surrogate endpoints in a broad range of areas for therapeutic development [19,20]. Progress in these areas have augmented industry knowledge of application of biomarkers in clinical development programs and fostered harmony with international regulatory organizations in the ever-expanding global research environment. This program has been making progress on expanding the toolbox for clinical development—many of the components foster development and application of biomarkers. As an example of international coordination among regulatory bodies, recently the FDA and the European Medicines Agency (EMEA) for the first time worked together to develop a framework allowing submission, in a single application to the two agencies, of the results of seven new biomarker tests that evaluate kidney damage during animal testing of new drugs. The new biomarkers are KIM-1, albumin, total protein, $\beta_2$-microglobulin, cystatin C, clusterin, and trefoil factor-3, replacing blood urea nitrogen (BUN) and creatinine in assessing acute toxicity [21]. The development of this framework is discussed in more detail by Goodsaid in Chapter Characterization and Validation Biomarkers in Drug Development: Regulatory Perspective.

In 2007, Congress established legislation that formed the Reagan–Udall Foundation, a not-for-profit corporation to advance the FDA's mission to modernize medical, veterinary, food, food ingredient, and cosmetic product development, accelerate innovation, and enhance product safety. Another important policy in biomarker development occurred with the above-mentioned establishment of the Critical Path Institute in 2006 to facilitate precompetitive collaborative research among pharmaceutical developers. In working closely with the FDA, these collaborations have focused on toxicology and therapeutic biomarker validation [22]. In 2007, a new collaboration building on public–private partnerships with industry was formed to develop clinical biomarkers. In 2006, the Biomarkers Consortium was established as a public–private initiative with industry and government to spur biomarker development and validation projects in cancer, central nervous system, and metabolic disorders in its initial phase [23]. These programs all support information exchange and optimize the potential to apply well-characterized biomarkers to facilitate pharmaceutical and diagnostic development programs.

Other policies that are broadening the dissemination of research findings relate to the growing directions toward open-source publishing. In 2003, the Public Library of Science began an open-source publication process that provides instant access to publications [24]. Many scientific journals have moved to make their archives available six to 12 months after publication. In 2008, the National Institutes of Health implemented policy that requires publications of scientific research with U.S. federal funding to be placed in the public domain within 12 months of publication [25]. All of these policy actions are

favoring biomarker research by accelerating the transfer of knowledge from discovery to development. New commercial management tools have been developed to provide extensive descriptions of biomarkers and their state of development. Such resources can help enhance industry application of well-characterized descriptive information and increase efficiency of research by avoiding duplication and establishing centralized credentialing of biomarker information [26].

New business models are emerging among industry and patient advocacy organizations to increase the diversity of financing options for early-stage clinical development [27]. Private philanthropy conducted with key roles of patient groups are supporting research in proof-of-concept research and target validation with the expectation that these targeted approaches will lead to commercial interests in therapeutic development. Patient advocacy foundations are supporting translational science in muscular dystrophy, amyotrophic lateral sclerosis, juvenile diabetes, multiple myeloma, and Pompe disease, often with partnerships from private companies [28,29].

## CHALLENGES AND SETBACKS

While progress in biomarker R&D has accelerated, the clinical translation of disease biomarkers as endpoints in disease management and as the foundation for diagnostic products has had more extensive challenges [30]. For example, we have not observed a large number of surrogate endpoints emerging as clinical trial decision points. Notable exceptions to this include imaging endpoints that have grown in substantial numbers. In most cases for drug development, biomarkers are being applied in therapeutic development to stratify patients into subgroups of responders, to aid in pharmacodynamic assessment, and to identify early toxicity indicators to avoid late-stage failures in therapeutic development.

There are difficulties in aligning the biomarker science to clinical outcome parameters to establish the clinical value in medical practice decision making. As applied in clinical practice, biomarkers have their most anticipated applications in pharmacotherapeutic decisions in treatment selection and dosing, risk assessment, and stratification of populations for disease preemption and prevention. In the United States, challenges to the marketplace are presented by the lack of extensive experience with pathways for medical product review and reimbursement systems that establish financial incentives for biomarker development as diagnostic assays. Clinical practice guidelines for biomarker application in many diseases are lacking, leaving clinicians uncertain about what roles biomarker assays play in disease management. In addition, few studies have been done to evaluate the cost-effectiveness of inclusion of biomarkers and molecular diagnostics in disease management [31]. The lack of these key pieces in a system of modern health care can cripple plans for integration of valuable technologies into clinical practice.

Scientific setbacks have also occurred across the frontier of discovery and development. Among notable instances was the use of pattern recognition of tandem mass spectrometric measurements of blood specimens in ovarian cancer patients. After enthusiastic support of the application in clinical settings, early successes were erased when technical errors and study design issues led to faulty assumptions about the findings. Across clinical development areas, deficiencies in clinical study design have left initial study findings unconfirmed, often due to overfitting of sample size to populations, and improper control for selection and design bias [32].

Commercial development of large-scale biology companies has also struggled in some ways to identify workable commercial models. Initial enthusiasm early in the decade about private marketing of genomic studies in disease models faltered as public data resources emerged. Corporate models for developing large proteomic databases faltered based on a lack of distinguished market value, little documented clinical benefit, and wide variability in quality of clinical biospecimens.

Evidence development to support clinical utility of many biomarkers to be used as clinical diagnostics is difficult to establish, as clinical trial infrastructure has not yet been established to validate candidate biomarkers for clinical practice. An obstacle to this has been access to well-characterized biospecimens coupled with clinical phenotype information. This has led to calls for centralized approaches to biospecimen collection and archiving to support molecular analysis and biomarker research [33]. Furthermore, a wide variety of tissue collection methods and DNA and protein preparation for molecular analysis has been at the root of many problems of irreproducibility. Standards development and best practices have been represented as cornerstones in facilitating biomarker validation [34,35]. Similarly, reacting to the lack of reproducibility of findings in some studies, proposals have been made for standards in study design for biomarker validation for risk classification and prediction [36].

## LOOKING FORWARD

The next decade of biomarker research is promising, with a push toward more clinical applications to be anticipated. Key factors on the horizon that will be integral to clinical adoption are summarized in Table 3. The confluence of basic and translational research has set the stage for *personalized medicine*, a term of art used widely now, which indicates that health care practices can be customized to meet specific biological and patient differences. The term was not part of the lexicon in 1997 but speaks to the consumer-directed aspects of biomedical research. Genomic services offered to consumers have emerged with the use of GWASs, although clinical value and impact are not known. It is clear that the emergence of biomarkers in an ever-changing health care delivery system will in some fashion incorporate the consumer marketplace.

**TABLE 3 Looking Ahead: Implementing Biomarkers in Clinical Care**

| Dynamic forces in industry financing |
| Co-development of diagnostics and therapeutics |
| Clinical infrastructure for evidence development and clinical utility of diagnostics |
| Health information exchange and network services |
| Consumer genomic information services |

Prospects for biomarkers to continue to play a major role in the transformation of pharmaceutical industry research remain high as new technology platforms, bioinformatics infrastructure, and credentialed biomarkers evolve. The emergence of a clearer role for federal regulators and increased attention to appraisal of value from genomic-based diagnostics will help provide guideposts for investment and a landscape for clinical application. One can anticipate that the impact of genomics in particular will probably provide a clinical benefit in chronic diseases and disorders, where multiple biomarker analyses reflect models and pathways of diseases. An emerging clinical marketplace is evolving for the development and application of biomarker assays as clinical diagnostics. The pathway for laboratory-developed tests will probably evolve to include FDA oversight of certain tests with added complexity of multiple variables integrated into index scoring approaches to assist in therapeutic selection. Clinical practice guidelines are beginning to emerge for the inclusion of biomarkers to guide stratification of patients and therapeutic decision making. The early impact of these approaches is now evident in oncology, cardiovascular, and infectious disease and immune disorders.

Advancing clinical biomarker to improve safety and quality of health care as a mainstay remains many years away. The clinical evaluation processes for diagnostics and targeted molecular therapy as a systematic approach have not yet been firmly established. The use of electronic health information, and integration of information from health plans and longitudinal data collection and randomized clinical trials will need integration and coordination for effective implementation in medical decision making.

In 2008, the first impact was felt for over-the-counter or electronically available consumer services based on genetic tests. Utilizing public and private genome-wide association databases, private-sector resources using powerful search engines coupled with family history information and SNP analysis developed a consumer service that identifies possible health risks. Although

the medical benefit of such services remains undocumented, the successful entry of several services and the growth of online commercial genomic services indicates interest among health-conscious citizens for understanding inherited disease risk. Another noteworthy factor that will probably play an important role in the next decade of clinical biomarker adoption is the development of standards and interoperability specifications for the health care delivery system and consumers. Interoperable health record environments will probably provide more flexibility and mobility of laboratory information and provide advantages to consumer empowerment in prevention and disease management.

One of the most important and sweeping challenges with biomarkers is the development of intellectual property policies that will bring opportunity and entrepreneurship in balance with meeting unmet market needs and clinical value. Because of the likelihood that single gene mutations or simple protein assays are not by themselves a discovery equivalent to diagnostic tests or new clinical markers, the arraying of the convergence of circles of technologies and knowledge will need new approaches to management for the combined aspects of technology to be brokered as real value in health care. Indeed, the challenges ahead in noting the importance overall for this notion is underscored more globally by Alan Greenspan in noting that "arguably, the single most important economic decision our lawmakers and courts will face in the next twenty-five years is to clarify the rules of intellectual property" [37].

Overall, a decade's worth of work has charted a robust and vibrant course for biomarkers across the biomedical research and development landscape. Clinical applications of biomarkers in medical practice are coming more into focus through diagnostics and molecularly targeted therapies, but a long period of time may pass before biomarker-based medicine becomes a standard in all areas of health care practice.

*MDS Pharma Services, Montreal, Quebec, Canada*

## UNDERSTANDING RISK

There is no question that most people who know something about our industry consider developing a drug product as a risky business. Usually, they mean that the investment of time and money is high while the chance of a successful outcome is low compared to other industries that create new products. Yet the rewards can be great, not only in terms of monetary return on investment (ROI) but also in the social value of contributing an important product to the treatment of human disease.

*Risk* is defined as "the possibility of loss or injury" [1]. Therefore, inherent in the concept is the mathematical sense of probability of occurrence of something unwanted. Everyday decisions and actions that people take are guided by conscious and unconscious assessments of risk, and we are comfortable with compartmentalized schemes where we sense that a situation is very high, high, medium, low, or very low risk. We often deal with the concept of a relative risk (e.g., in comparison to other options). Some risks can be defined in more absolute terms, such as some type of population measure based on trend analysis of prior incidence statistics (e.g., current risk of postmenopausal Caucasian women in the United States being diagnosed with breast cancer).

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

These types of population-based risk data, while often much debated in the scientific and popular press, do affect decision making at the individual level.

As opposed to an individual's skill at assessing risks, decisions and actions taken during drug development require objective and systematic risk assessment by groups of people. There are many stakeholders involved in the development of a drug product. These include the specialists that do the science required in drug development. Also included are the investors and managers who make decisions about how limited resources will be used. Clinical investigators who administer the drug and the patients who agree to participate in clinical trials are stakeholders, as are the regulators and institutional review boards (IRBs) or ethics committees that approve use of an experimental drug in humans. Each stakeholder has his or her unique perspective of risk. The prime focus of some is the business risk involved, including how much work and money is invested to progress the drug at each phase of development. On the other hand, IRBs, regulators, investigators, and patients are concerned primarily with the safety risk to the patient.

Figure 1 depicts the major factors that contribute to three different perspectives of risk, broadly classified as risk to patient, business risk, and risk of therapeutic failure. Investigators and patients are concerned primarily with safety and efficacy factors associated with a particular therapy. Although regulators are concerned primarily with patient safety, regulations do affect how much development will be required for a particular drug candidate. The business risk can be greatly affected by the investment and development partners involved and the expectations set with owners and managers. Potential competitors in the marketplace affect risk, as does the available pool of money for development. The common factor for all three risk perspectives is the novelty

**Figure 1** Major factors affecting three main perspectives of risk in drug development: business risk, risk to patient, and risk of therapeutic failure.

of the product. Drug candidates that represent new targets for therapy while representing a hope for improved efficacy do require more interactions with regulators and investigators, adding to development expense. In addition, because the target is unproven, there is a greater relative risk for therapeutic failure compared to proven pharmacological targets of disease intervention. Therefore, when attempting to express the risks involved in developing a drug, it is important to understand the varying perspectives of each major group of stakeholders.

Before risk assessment can be fully appreciated in the context of decision making in drug development, it must be balanced with the perceived benefits of the product. For example, the patient and physician would tolerate a high level of risk to the patient if the potential benefits offered by a novel therapeutic are for a life-threatening disease for which there is no effective treatment. In a similar way, a high degree of business risk may be tolerated by investors in novel drug candidates if the return on investment, if successful, were very high. Like risk, benefits are also in the eye of the beholder.

Ideally, on many occasions during drug development, each stakeholder is asked to assess his or her view of risk versus benefit based on current data. This assessment will become part of the decision-making process that drives drug development in a logical and, hopefully, collaborative way. Effective decision making requires integrating these varying risk–benefit assessments in a balanced way. The decision gate approach is a useful way to integrate these needs into the drug development process.

## DECISION GATES

Drug development is a process that proceeds through several high-level *decision gates* from identification of a potential therapeutic agent through to marketing a new drug product [2]. A decision gate is a good analogy. For a drug candidate to progress further in drug development it must meet a set of criteria that have been agreed to by the decision makers before they will open the gate. It is "go/no go" because the future product life of the drug hangs in the balance. Once a new drug candidate has progressed through a decision gate, the organization should be committed to expend even greater resources (money and scientists' time) to do the studies to address criteria for the next decision gate along the development path.

Disciplined planning and decision making is required to leverage the value of the decision gate approach. An example of a decision grid applicable to the early phase of drug development is depicted in Table 1. Initially, a clear set of questions at each decision gate needs to be agreed upon and understood by the decision makers. In later stages of drug development these questions and criteria are often presented in a *target product profile* (TPP), which is, in essence, a summary of a drug development plan described in terms of labeling concepts. The FDA has formalized the agency's expectations for a TPP in a

**TABLE 1 Decision Gate Grid Defining Criteria Required to Move Through the Decision Gate "Safe to Give to Humans?"**

| | Efficacy | Animal Safety | PK/ADME | CMC | Phase I Study Design |
|---|---|---|---|---|---|
| Best achievable (enhance investment) | Rodent model: $ED_{90}$<0.3 mg/kg; human receptor: $IC_{50}$<1 μM | Rodent: NOAEL >50 mg/kg; dog: NOAEL >50 mg/kg; no genotoxicity; no CV effects | Dog half-life >8 h; dog BA >90%; no active metabolites; no *CYP2D6* inhibition | API stable for at least 6 mo Cost of goods for API <$10 K/kg GMP tablet | Cohorts of healthy normal subjects: staggered (SD to MD) dose escalation; normal safety monitoring |
| Base case (invest in next phase) | Rodent model: $ED_{90}$<1 mg/kg; human receptor: $IC_{50}$<10 μM | Rodent: NOAEL >10 mg/kg; dog: NOAEL >10 mg/kg; no genotoxicity no CV; effects <100 mg/kg | Dog half-life >4 h; dog BA >50%; <10% active metabolites; *CYP2D6* inhibition: $K_i$>10 μM | API stable for at least 3 mo Cost of goods for API <$20 K/kg GMP tablet | Cohorts of healthy normal subjects: sequential dose escalation; intensive CV monitoring |
| Minimum required (proceed with caution) | Rodent model: $ED_{90}$<2 mg/kg; human receptor: $IC_{50}$<50 μM | Rodent: NOAEL >5 mg/kg; dog: NOAEL >5 mg/kg; equivocal genotoxicity at highest exposure; no CV effects <30 mg/kg | Dog half-life >2 h; dog BA >30%; <30% active metabolites; *CYP2D6* inhibition: $K_i$>1 μM | API stable for at least 3 mo Cost of goods for API <$30 K/kg GMP tablet | Patients: multisite dose escalation; intensive CV monitoring; FDA review after each dose escalation |

guidance document [3]. Many companies start evolving a TPP even at the earliest go/no go decision gates of drug development. In this way, a common way of thinking is preserved throughout the life of the product. The development program plan is assembled by determining what studies need to be done and their design that would provide information critical to answering the key questions at each go/no go decision gate.

The value of a solid drug development plan based on a decision gate approach can be leveraged only if there is discipline in the decision-making process. What method will be used to make a decision: a majority vote of a committee or a single decider who is advised by others? Each stakeholder needs to understand clearly his or her role in making the decision at each gate. Is he or she a decider, a consultant, or just someone who needs to know what the decision is in order to do the job effectively? Go/no go decisions need to be made when all information required to answer the key questions is available. Go/no go decisions should not be revisited. If this occurs, there is either a lack of decision discipline or key information was missing when the original decision was made, representing a failure in planning.

Some go/no go decision gates require agreement to proceed by different groups of stakeholders. This is particularly true when the question "Is the drug candidate safe to give to humans?" is addressed. The sponsor must decide whether to file an investigational new drug (IND) application based on the data and information collected so far from animal tests and in vitro assays. The same data are also evaluated by the regulators (e.g., the FDA), who must have time (30 days) to object if they feel the safety of the subjects in the first few clinical trials will be compromised unduly. Finally, the data are reviewed again by the IRB, who look specifically at how safety will be evaluated and managed in the clinical trials and who represent the interests of the volunteers. It is as if the gate has three locks, each with a key owned by a separate entity which will decide independently whether they open their lock. One cannot pass through the gate until all three locks are open.

## ROLE OF BIOMARKERS IN DISCOVERY AND PRECLINICAL DEVELOPMENT

Less than 10% of drug candidates that enter clinical testing result in a marketed product [4]. This means that at some point during clinical development over 90% of drug candidates fail. If failure occurs late in clinical development, up to hundreds of millions of dollars and a great deal of time and effort will have been invested, with little or no return. Proper incorporation of biomarkers in drug development strategy enables the concept "fail fast, fail early." Early failure actually lowers overall risk because it enables one to move resources and utilize available patients on other promising therapies.

Biomarker data can be critical to a go/no go decision. By definition, biomarkers may reflect the biology or the progression of disease and/or the effect

of drug treatment. Therefore, information provided by properly selected biomarkers can greatly influence the decision as to whether or not to progress through a go/no go decision gate. The challenge is to identify relevant biomarkers early enough to implement them for go/no go decisions at the critical early stages of the discovery–development process.

Biomarkers in discovery are valuable tools for understanding the pathobiology of a disease and the pharmacology of a target and/or compounds (hits or leads) under investigation. Moreover, even at this very early stage, a biomarker may already be identified as a potential clinical safety or efficacy biomarker. Decision gates in discovery are frequently directed toward selection of a lead or a small number of leads to take forward to preclinical development, and prioritization of the leads. For this purpose, a number of commonly employed screening assays can generate useful biomarker data. For example, membrane permeability coefficients and metabolic stability data from *Caco-2* and hepatocyte screening assays, respectively, are predictive biomarkers of in vivo intestinal absorption and liver metabolism, and can be used to weed out compounds unlikely to have acceptable pharmacokinetic (PK) properties for the clinical use intended.

During preclinical development, the focus of studies is on revealing potential toxicity of the drug candidate. Accordingly, there is interest in identifying and monitoring safety biomarkers that can be used for go/no go decisions. Particularly for classes of compounds whose development has been plagued by unusual findings in animals that have not translated into human risk (e.g., fibrates and peroxisome proliferation in rodents), safety biomarkers that translate well across species are highly desirable but not always easy to find.

In both discovery and preclinical development, the abundance of new technologies, high content screening, imaging, genomics, proteomics, metabonomics, and systems biology, to name a few, has opened the door to the identification of theoretically innumerable novel biomarkers along with an expectation that this will result in enhanced efficiency and better decision making. However, the technologies, and the biomarkers that they produce, have to be evaluated as to how they provide insight into understanding the biology and pharmacology being investigated, and how they can be used effectively by scientists and managers in decision making. As discussed in Chapter Imaging as a Localized Biomarker: Opportunities and Challenges, increased volume and complexity of data require sophisticated data analysis and informatics infrastructure to be in place before the new knowledge generated can be applied meaningfully to decision making.

## ROLE OF BIOMARKERS IN EARLY CLINICAL RESEARCH

Biomarkers may be the only way to address a decision gate that asks the question: Is there evidence that the drug is working in humans using the same

mechanism of action defined by animal studies? This question is answered by a clinical proof-of-concept study: often, a phase IIa study in a small number of patients. However, occasionally, clinical proof of concept can be addressed during phase I development if the mechanism of action can be demonstrated in healthy volunteers (e.g., effects on blood pressure, body weight, lipids). The changes in the data collected during this study do not achieve statistical significance; rather, there needs to be enough indication of potential efficacy to convince decision makers to open the gate and spend the resources to progress the drug further. Often, the minimal result for progression can be defined ahead of time, making the actual decision-making process much easier, more objective, and transparent.

Early in clinical development, multiple biomarker assays or technologies may be utilized in order to understand more fully the safety and actions of the drug in humans. One may use a collection of biomarker methods, most of which are not likely to be fully validated surrogate markers of effect. For early decision making, it is not necessary to have results that meet the same standards of accuracy and quality as those used for drug approval. Indeed, it is during these early trials that promising tests for use in later clinical development or marketing are first identified from among the pool of available experimental biomarkers. Resources can then be put to further developing the selected biomarker methodology to meet the quality standards expected for continued future use.

Knowledge of the biology of the disease may be evolving at the same time as the drug is being developed. Therefore, new biomarkers may need to be added during the development process as the science evolves. It should not be assumed that the "tried and true" biomarkers are the only ones worthy of consideration or that a biomarker that was used to obtain marketing approval in the past is the one that should be used today. Good science supported by convincing data can convince stakeholders that a novel biomarker is better than one already established.

## ROLE OF BIOMARKERS IN PHASE III AND POSTMARKETING DECISIONS

Traditional clinical trial endpoints, such as morbidity and mortality, often require extended time frames and may be difficult to evaluate. Fully validated surrogate markers can be used as primary endpoints for pivotal phase IIb and III safety and efficacy trials. Lowering blood pressure and lowering LDL cholesterol are both examples of surrogate biomarker endpoints upon which several drugs have been approved, because it has been demonstrated that effects on these markers directly affect morbidity and mortality several years later.

New technologies are now rapidly emerging that show similar promise in providing efficacy signals earlier in the treatment of certain slowly progressing diseases. Imaging-based biomarkers are providing objective endpoints that may be confidently evaluated in a reasonable time frame. Imaging techniques tend to be expensive, but can be cost-effective when used in well-defined situations where subjective assessment has been the only approach available. As discussed in greater detail elsewhere in this book, examples of therapeutic areas where imaging is reshaping clinical trial design include Alzheimer disease, pain, and osteoarthritis. In affected joints, as well as in tissues expressing specific receptors, magnetic resonance imaging, x-ray computed tomography, position-emission tomography, and single-photon-emission computed tomography imaging are delivering new information to clinicians and researchers.

Patient selection is another area where decisions are made using biomarker information. For example, in developing Herceptin, patients who tested negative for the *Her2Neu* receptor responded poorly to drug treatment, whereas good effects were observed in patients who expressed the receptor. This is consistent with the mechanism of action of the drug and resulted in regulatory approval for patients positive for *Her2Neu*. The outcome was that a diagnostic test was required before this drug could be marketed effectively. So this is now a biomarker that drives the treatment decisions of breast cancer oncologists around the world.

Identifying potential responders or nonresponders prior to phase III clinical trials can have a profound effect on the size of a clinical trial. Eliminating nonresponders can dramatically reduce the intersubject variability in response, thereby reducing the number of subjects in each group of a pivotal clinical trial required to demonstrate effect. The result is a saving in time and large savings in costs. However, if the biomarker is novel, a diagnostic will need to be developed along with the drug before one can market the product effectively.

## SUMMARY

Biomarkers have the potential to provide valuable information that can be translated into knowledge to aid decision making at all stages of the drug discovery–development process. Different stakeholders have different perspectives of risk associated with development and clinical use of a drug. Although biomarkers cannot eliminate the inherent challenges to integrating risk assessment in this complex environment, the associated data can be evaluated objectively. As informatic tools evolve to analyze more efficiently and effectively the large data sets associated with the new biomarker technologies, decision making, in turn, will become better. Regardless of the technologies employed and the complexity of data, a disciplined planning and decision-making process is essential to successful drug development.

## INTRODUCTION

Medical imaging is well known for its ability to produce pictures of patient anatomy for the diagnosis of disease, but perhaps more significant for drug development is its ability to produce images of physiological and physicochemical processes in a living subject. It is the latter that gives rise to the concept of imaging biomarkers, which we may define as the subset of all biomarkers that utilize medical imaging technologies to acquire data. Medical imaging technologies include a range of modalities used in a routine clinical setting: x-ray computed tomography (CT), positron-emission tomography (PET), single-photon-emission computed tomography (SPECT), magnetic resonance imaging (MRI), ultrasound, and optical imaging.

In its 2006 Critical Path Opportunities Report, the U.S. Food and Drug Administration (FDA) defined *biomarkers* as "measurable characteristics that

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

reflect physiological, pharmacological, or disease processes in animals or humans. Changes in biomarkers following treatments reflect the clinical response to the product. Biomarkers can reduce uncertainty by providing quantitative predictions about performance" [1]. In this chapter we will discuss imaging as a localized biomarker. Although imaging biomarkers hold great potential for accelerating drug discovery and development, in practice they are often difficult and costly to implement for specific applications, may be used inappropriately in a development setting, or may fail to provide a robust answer to the development questions being asked. We focus our discussion on understanding the opportunities for using imaging biomarkers as tools in drug development while recognizing the current challenges and how efforts to overcome these challenges are evolving.

We begin by presenting a brief overview of biological imaging. Then we discuss the general characteristics and context of an imaging biomarker along with key advantages and limitations of imaging biomarkers. We place the definition of a biomarker given above into the context of biological imaging in general and diagnostic medical imaging in particular. We follow this with an overview of the scope of imaging in drug development, highlight specific examples of established and emerging imaging biomarkers from oncology that have found utility in drug development and illustrate considerations for imaging biomarker selection. A key issue in the implementation and use of imaging biomarkers is the challenge of standardization which we then examine in some detail. We conclude by discussing current efforts to address the unique needs of imaging biomarker development.

## OVERVIEW OF IMAGING IN BIOLOGICAL RESEARCH

From their inception, the various noninvasive imaging modalities have been used widely in basic biological research. The broad utility of imaging in biological research reflects the breadth of fundamental physical processes that underlie all imaging technologies. The same types of probes and methods of detection that are used in biochemistry and in molecular and cellular biology [e.g., optical, nuclear (gamma emission), nuclear magnetic resonance (NMR) spectroscopy, x-ray] also form the basis of imaging technologies. When the electron microscope was introduced in the 1930s, the morphology of submicroscopic cellular structures that had only been inferred by indirect methods such as x-ray diffraction or structural chemistry could be visualized directly for the first time in electron micrographs [2]. By analogy, the development of medical imaging technologies (e.g., SPECT [3], PET [4,5], CT [6], and MRI [7,8]) has provided the ability to visualize in vivo biological processes previously accessible only by indirect or invasive means. As the science of biological imaging has grown, the development of new imaging applications has been driven by the unique ability of noninvasive imaging to reveal information

about anatomical structure and physiological function as well as various disease states in living subjects.

It will be helpful to review briefly the use of imaging in biological research in order to understand the context and source of imaging biomarkers. We describe some common clinical imaging technologies and then highlight some of the image-based methods for measuring biological function that have been proposed in the literature, providing a background for detailed examples. Several examples of biological imaging applications in drug discovery are also provided in a recent monograph [9].

## Clinical Imaging Technologies

Although we limit our discussion here to nuclear PET and SPECT, CT, and MRI modalities, the following applies equally well to other imaging technologies, including ultrasound, which is widely used clinically, and various forms of optical imaging which are becoming more prevalent [10]. An accessible general introduction to imaging technologies is available [11], as is a comprehensive treatment of the theoretical basis of imaging [12].

CT, the most commonly used clinical imaging modality, provides three-dimensional images of anatomical structure. The main source of contrast in CT images arises from the differential attenuation of x-rays by tissues in the body. In CT images, mineralized tissues appear brighter due to higher attenuation of the x-rays, and soft tissues have intermediate intensity due to lower attenuation. Because of limited contrast differences between soft tissues, an injectable iodine-based contrast agent is often necessary to better highlight anatomical lesions. Despite this limitation, CT provides the highest spatial resolution (less than 0.5 mm), and acquisition of CT data is straightforward and rapid.

MRI may be characterized as a large family of methods to detect molecular- and cellular-dependent image contrasts through the manipulation of nuclear spin magnetic resonance during data acquisition. The proton nuclei of hydrogen in water and lipids are the most commonly imaged, although in principle the NMR basis of detection permits imaging or spatially localized spectroscopy of other nuclei, such as $^{13}C$, $^{19}F$, $^{23}Na$, and $^{31}P$. The sensitivity of MRI is relatively poor, generally requiring tens of micromolar to millimolar volumes of nuclei for detection. However, excellent soft tissue contrast with high spatial resolution (ca. 1 mm) may be obtained. Acquisition of MRI data is controlled by a pulse sequence, which is a computer program that orchestrates the transmission of radio-frequency pulses and magnetic field gradients, as well as the reception of radio-frequency signals from the subject [13]. Vendor-supplied pulse sequences provide a broad range of available acquisition methods; however, additional pulse sequences and improved methods are constantly being introduced in MRI research.

While MRI applications tend to be focused on the seemingly limitless variations in MR acquisition methods, data acquisition in nuclear imaging (PET

and SPECT) is relatively straightforward, being based on either detection of single gamma photons (SPECT) or coincident collinear pairs of gamma photons (PET). Image contrast in nuclear imaging relies on the use of targeted biomolecular probes or tracers labeled with radionuclides to detect in vivo molecular processes and biological function. Thus, the scope of radionuclide imaging is limited primarily by the ability to efficiently radiolabel biologically relevant molecules, and applications are centered primarily on the skill and creativity of the radiochemist. In general, the sensitivity of nuclear imaging methods is the highest of all clinical modalities, with the picomolar sensitivity of PET being about two to three orders of magnitude higher than that of SPECT [14]. The low intrinsic resolution of PET (ca. 5 mm) and SPECT (ca. 15 mm) has been mitigated somewhat through the development of multimodality image acquisition combining PET/CT or SPECT/CT [15], and more recently PET/MRI [16], which provide high-resolution anatomical images registered with functional nuclear images.

In all imaging modalities, the resulting images must be reconstructed from the data acquired using computational methods of varying complexity [17,18], and additionally, in some cases, a series of images may be used to calculate parametric images representing image-based measures corresponding to particular biological functions.

## Image-Based Measures of Biological Function

Many imaged-based measures of biological and physiological function have arisen in imaging and medical research. For example, the Center for Biomarkers in Imaging (http://www.biomarkers.org) makes available an online catalog of approximately 350 image-based biological measures that have been investigated primarily at Massachusetts General Hospital in Boston. Apart from differences in modality, such image-based measures may be classified into three general types according to the way in which image contrast is generated: by endogenous biophysical mechanisms, exogenous contrast agents, or molecular probes [19]. For example, endogenous contrast can be produced by differences in MRI relaxation times such as $T_1$, $T_2$, $T_2^*$, macromolecular cross-relaxation, or transport mechanisms such as blood flow, perfusion, and diffusion. These contrast mechanisms are often enhanced by the use of exogenous contrast agents in CT and MRI as well as ultrasound. Table 1 lists some examples of endogenous and contrast agent–enhanced biological measures using MRI. Numerous other MRI approaches providing image-based measures of disease processes are available [20], as well as MRI-based measures specific to diseases of the brain [21].

Imaging with the use of molecular probes, known as *molecular imaging* [22], also involves the injection of an exogenous agent to provide image contrast. In this case the imaging agent is designed for cellular uptake or binding with a high affinity for a specific in vivo molecular target or process [23]. Molecular imaging is able to provide new information on disease processes not available

**TABLE 1 Examples of Image-Based Measures of Biological Function in MRI Using Endogenous Mechanisms or Exogenous Contrast Agents**

| MRI Imaging Method[a] | Image-Based Measure or Parameter | Biological Function or Parameter | Reference |
|---|---|---|---|
| DSC bolus tracking | $T_2$- and $T_2^*$-weighted intensity changes | Relative cerebral blood volume, relative cerebral blood flow, mean transit time | [149] |
| BOLD | $T_2$- and $T_2^*$-weighted intensity correlation with stimulus | Task-induced functional activation in the brain | [195] |
| ASL | Difference between spin-inverted and control images | Blood flow | [149] |
| Chemical shift encoding | Phase-shifted images from water–fat chemical shift | In vivo water distribution, in vivo fat distribution | [196] |
| $T_2$-weighted MRI | Integral increase in $T_2$ values | Peripheral edema | [70] |
| | Weighted sum of biexponential $T_2$ values | Liver iron concentration | [197] |
| MRTI | Temperature-dependent proton resonance frequency shift | In vivo temperature distribution | [198] |
| CEST/ PARACEST | Amide proton transfer | Spatial distribution of pH | [199,200] |
| CEST | Amide proton transfer | Glycogen concentration | [201] |

[a]DCS, dynamic susceptibility contrast; BOLD, blood-oxygenation-level-dependent; ASL, arterial spin labeling; MRTI, magnetic resonance temperature imaging; CEST, chemical exchange saturation transfer.

from other methods. For example, molecular imaging was used recently to establish the relationship between inflammation and microcalcification in early-stage atherosclerotic plaques [24]; it has been used to visualize the in vivo spatial distribution and time course of vascular endothelial growth factor receptor expression in a model of peripheral arterial disease [25]; and it has been combined with conditional disease models using transgenic mice and genetic profiling to yield a powerful system for in vivo preclinical study of disease processes and potential therapeutic targets [26–29]. The most common molecular imaging applications utilize radiolabeled tracers for detection by the nuclear modalities. However, many nonnuclear approaches have also been developed with optical [10], MRI [20,22], and ultrasound modalities [30,31].

The majority of such image-based measures are distinguished from direct imaging of anatomy by being connected indirectly to the biology. A biological,

biophysical, or molecular model is introduced to provide a bridge from the specific image contrast to the physiology, and a correlation is typically established using invasive (nonimaging) or histological measures. In the case of molecular imaging, the model is represented by the underlying signal generation and targeting mechanisms of the probe, which may be verified independent of the imaging experiment. In other cases, the model is implicit and an empirical correlation provides only a phenomenological link between the image-based measurement and a physiological parameter or process. The invasive or histological correlate often provides an initial rationale for the imaging approach, and may guide development of a model and subsequent interpretation of the measurements.

It is helpful to think of such methods as image-based noninvasive assays, in the sense that the measurements extract or infer some biological, physiological, or molecular characteristic from the subject as a whole. Although not always clinically diagnostic for disease, such image-based assays can often provide the ability to monitor disease progression [19]. The associated biological or biophysical models provide widely varying degrees of linkage between measurement and biology. Molecular imaging provides perhaps the most direct linkage since the characteristics of target, signal generation, and the probe's affinity for the target can be determined empirically, leading to relative confidence in the functional or molecular basis of the image-based signal. The use of [$^{18}$F]fluorodeoxyglucose, a glucose analog, as a radiotracer in PET imaging relies on the empirical facts of glucose uptake and phosphorylation by metabolically active cells. In other cases, a single image-derived parameter corresponds to a complex of multiple functional parameters. For example, kinetic modeling of dynamic contrast-enhanced (DCE) MRI data produces a model parameter, $K^{\text{trans}}$, that can be influenced by several factors, such as blood flow, vascular permeability, and vascular surface area, potentially complicating interpretation of this image-based measure.

Even when an explicit biophysical model is available, as is the case for magnetization transfer MRI [32], it may be impractical to acquire the image-based measurements necessary to apply that model. In this particular case, a related phenomenological model has proven useful to relate a simpler measurement (the magnetization transfer ratio) to the diffuse macromolecular changes and demyelination associated with multiple sclerosis [33]. The lack of specificity of some image-based measures warrants caution in their use prior to adequate assay validation. Early ex vivo NMR measurements of bulk $T_1$ and $T_2$ relaxation of tumors [34] were initially believed to distinguish malignancy from nonmalignancy, and even inspired development of the first whole-body MRI system [35]. However, these results have not subsequently be validated in vivo, although several other MRI methods for characterizing tumors and evaluating therapy have since been developed [36]. Anatomical and structural imaging can also provide functional measures if appropriate image quantification is applied, such as measuring tumor size or volume, which leads to an image-based measure of tumor growth.

Despite the exploratory nature of many imaging research applications, the diversity of image-based functional measures often furnishes much of the interest and enthusiasm for potential imaging biomarkers. However, numerous additional factors must be addressed to establish the reliability, validity, and suitability of a particular image-based measurement as a tool for evaluating novel therapeutics.

## ANATOMY OF AN IMAGING BIOMARKER

Like the drug development process itself, developing, implementing, and using imaging biomarkers is a highly collaborative multidisciplinary effort. As depicted in Figure 1, an imaging biomarker may be defined conceptually by two aspects: image acquisition and image analysis. *Image acquisition* refers to all activities and technologies related and leading to the acquisition of image data, such as imaging hardware operation, maintenance and quality control, subject positioning, contrast agent or radiotracer preparation, injection protocols, and physiological monitoring. *Image analysis* includes all postacquisition activities, such as image reconstruction, processing, quantification, and interpretation. These two aspects of an imaging biomarker require significant

**Figure 1** An imaging biomarker may be defined by its methods for image acquisition and analysis. Both aspects require input from numerous scientific and engineering disciplines.

input from a diverse array of scientific and engineering disciplines, including biology, chemistry, physics, biomedical and nuclear engineering, computer science, and mathematics as well as medicine. Each of these specialties has several critical roles in the implementation and use of imaging biomarkers:

- *Biologist/physiologist/molecular biologist/pathologist:* help establish the biological relationship between the image-based measurement and the physiological function or disease process; help establish the rationale for studying particular image-based measures; and help interpret the quantitative results.
- *Pharmacologist/physician/pathologist:* help establish the clinical relationship between the imaged-based measurement and the relevant therapeutic outcomes during treatment; and help understand all possible actions of the treatment (beneficial and deleterious) [37] to aid in the interpretation of imaging results.
- *Biochemist/radiochemist:* provide understanding of physiological processes and molecular targets at the biochemical level; and design, synthesize, characterize, and test optical, magnetic, and molecular probes and radiotracers.
- *Mathematician/statistician/computer scientist:* provide the fundamental mathematical, statistical, and quantitative basis for image acquisition, reconstruction, and analysis; and provide software tools for performing many tasks associated with image acquisition, reconstruction, quantification, analysis, visualization, and interpretation.
- *Imaging physicist/biomedical and nuclear engineer/technologist:* provide the physical basis for imaging technologies, signal generation and detection, hardware design, and optimization; provide the technological expertise for isotope production to be used for generating radiotracers; and operate the imaging equipment, performing image acquisition, processing, and analysis tasks.

## Essential Characteristics of Imaging Biomarkers

Earlier we highlighted the use of imaging in biological research. In such studies, when a correlation is demonstrated between an image-based measurement and a particular physiological characteristic or disease process, it is tempting to identify that measurement as an imaging biomarker. However, this is not always useful. Here we identify several additional characteristics of imaging biomarkers that will generally become essential as an image-based functional measure progresses through the process of validation and clinical qualification (Figure 2).

***Scientific Characteristics*** For an image-based measurement to be an effective tool in drug development, the "model" linking the measurement to a

**Figure 2** Two-step process for imaging biomarker validation/qualification. *Assay validation* establishes the link between the image-based measure and a specific biological function or disease process by way of a biological, biophysical, or molecular "model." This includes characterizing the measurement's intra- and interobserver and test–retest variability (measurement reliability), as well as correlating the measurement to an established (nonimaging or invasive) standard. The goal of the second step, *clinical qualification*, is to establish empirically, by clinical trials, the relationship between the image-based functional measure and a relevant clinical endpoint or outcome. (*See insert for color reproduction of the figure.*)

biological or disease process must be characterized, which is termed *assay validation*. This process includes:

- Characterizing the validity of the model by correlation with an accepted standard
- Characterizing the reliability of the measurement:
  - Intraobserver variability
  - Interobserver variability
  - Test–retest variability
- Defining the conditions under which the image-based measurement will result in the expected model validity and measurement reliability:
  - Biological conditions
  - State and stage of disease
  - Class of therapy
- Optimizing the image acquisition and analysis systems for the task of parameter *estimation* as opposed to *classification*

Basic research studies of image-based biological measures may provide only partial validation by attempting to establish the validity of the model and occasionally reporting some measure of reliability in a limited sample size,

often in preclinical studies. Additional development may be necessary to fully characterize and optimize the measure in both animal models and in humans. Like the underlying image-based methodology, the imaging biomarker is necessarily quantitative, which requires parameter estimation from the images, a process that should aim to be as efficient and objective as possible.

***Clinical Characteristics*** In addition to the scientific concerns of assay validation, several clinical issues must be addressed. The relationship of an image-based measure of biological function to a specified clinical endpoint must be established empirically through clinical trials, which may be termed *clinical qualification* (Figure 2). Clinical qualification seeks to:

- Define a relevant clinical endpoint or outcome
- Establish empirically the relationship between the image-based measure and the clinical endpoint
- Characterize the propagation of measurement uncertainty to uncertainty in clinical outcome
- Establish the safety of the imaging procedure

These aims are often hindered by the need for large amounts of data to support clinical qualification. The imaged-based measure may be more sensitive to biological changes than the corresponding clinical endpoint, reflecting fluctuations that are not clinically relevant; or the clinical endpoint might be somewhat subjective, subject to large variability, or require lengthy trials.

***Additional Criteria*** Apart from the scientific and clinical issues of biomarker qualification, further logistical and economic concerns must be addressed as an imaging biomarker progresses through clinical qualification.

- The necessary acquisition hardware, methods, and image analysis tools must be readily available.
- The image acquisition and analysis methods must be standardized across hardware platforms and imaging centers.
- The imaging biomarker must be cost-effective and efficient compared to other available imaging and nonimaging biomarkers with similar purpose.

***Development Stages*** It is clear that most imaging biomarkers today fall short of achieving all of these characteristics. To describe the development stage of imaging biomarkers, the FDA has identified four distinct classes of imaging biomarkers which are focused on drug development applications: *pre-biomarkers, biomarkers, surrogate biomarkers*, and *clinical diagnostic surrogate biomarkers* [38]. According to this classification, *pre-biomarkers* are those at an incomplete stage of assay validation; *biomarkers* are those that have completed assay validation along with an appropriate safety profile; *surrogate*

*biomarkers* are those for which sufficient clinical evidence exists to qualify the biomarker for use in drug development; and *clinical diagnostic surrogate biomarkers* are those that have been validated and qualified to such an extent as to be "integrated into an approved/licensed therapeutic regimen" and are able to "assure/improve safety and/or efficacy" [38].

Imaging biomarkers are useful tools for a variety of tasks in addition to drug development. Therefore, another perspective, which perhaps includes a wider spectrum of methods, is to stage imaging biomarkers according to their intended use [39]. There are at least four distinct *categories of use* for imaging biomarkers in the wider sense:

1. Elucidate biological function and disease processes in vivo (*basic biological research*).
2. Evaluate novel therapies in vivo for industry decision making (*drug development—industry decisions*).
3. Evaluate novel therapeutics in vivo for government licensure (*drug development—government registration*).
4. Enhance routine diagnosis of disease with better disease management, prognosis, and therapeutic decision making (*clinical practice*).

The four stages correspond roughly to the FDA imaging biomarker classes described above in terms of the level of validation and qualification within each stage (Table 2). They also parallel the conceptual biomarker hierarchy

**TABLE 2 Classification of Imaging Biomarkers According to Their Intended Use[a] and the Corresponding Stage of Validation and Qualification**

| Stage | Imaging Biomarker Intended Use | Assay Validation | Clinical Qualification | Additional Criteria[b] | Potential Impact[c] |
|---|---|---|---|---|---|
| 1 | Basic research | Partial | No | No | * |
| 2 | Drug development: industry decisions | Yes | Partial | No | ** |
| 3 | Drug development: government registration | Yes | Yes | Partial | *** |
| 4 | Clinical practice | Yes | Yes | Yes | **** |

[a]Intended uses are "backward compatible," in that an imaging biomarker that achieves a given stage of validation and qualification will fulfill the requirements for all preceding uses. Note that regulatory scrutiny would be limited to imaging biomarkers at stages 3 and 4.
[b]Nonscientific and nonclinical criteria, including logistical and economic issues such as availability of technology, standardization of methodology, and cost-effectiveness.
[c]At each development stage, the potential impact of an imaging biomarker on drug discovery and development and on human health.

suggested by Frank et al. [40] using the body of evidence supporting each class: *plausibility, correlation/association, predictive power,* and *cause*. The categories of "probable valid biomarker" and "known valid biomarker" suggested by the FDA [41] would be contained in stage 2, while stage 3 corresponds to "surrogate endpoints" [39].

These four categories of use emphasize that there may be an appropriate context and use of imaging biomarkers at each stage of validation or qualification. Basic biological research provides fundamental knowledge of disease processes as well as a ready source for new biomarker discovery; the use of imaging biomarkers in clinical practice clearly overlaps with the routine use of imaging in clinical diagnosis. The significance of these potential imaging biomarker uses is that they can be leveraged to facilitate further development and adoption of imaging biomarkers as drug development tools, particularly as surrogate endpoints for regulatory decision making.

## Imaging Biomarkers and Diagnostic Imaging

The foremost application of medical imaging is the routine clinical diagnosis of disease. Historically, the development of imaging systems capable of scanning humans followed shortly after the initial technological development of the various imaging modalities [3,5–7,35,42–44]. Moreover, medical imaging applications emphasizing medical diagnosis have driven much of the technological improvements to the present day.

Although the primary diagnostic purpose of medical imaging overlaps considerably with imaging biomarker applications, there are important distinctions between the context and goals of their use [45]. Diagnostic imaging is generally focused on detection of lesions or abnormality, and image assessments are usually made in a subjective, qualitative manner relying on the training and experience of a medical professional. In this case, the primary goal is the medical management of individual patients. By contrast, imaging biomarkers are focused on the quantitative characterization of disease which is generally already known to be present, with the aim of objectively measuring effects related to a medical treatment or intervention. Typically, serial measurements from one or more follow-up imaging sessions are compared to a baseline measurement, and measurements are collected from patient groups drawn from well-defined patient populations.

Why is it important to draw a distinction between imaging biomarkers and diagnostic imaging? It is widely recognized that the most reliable and objective approach to assess image quality, and thus optimize the imaging process, is, first, to specify the purpose or task for which the image is produced, and second, to determine quantitatively how well that task is performed [46]. Two general categories of tasks that relate to medical imaging are *classification* tasks, which are the typical diagnostic tasks of deciding whether a patient has or does not have disease, and *estimation* tasks, which involve estimating quantities of interest from medical images [46]. An example of a classification task

would be an oncologist using images to detect or locate abnormal lesions, and attempting to answer the questions: Are the lesions malignant or nonmalignant, and if malignant, what is the grade or stage of the cancer? Examples of estimation tasks would be a cardiologist estimating the extent and severity of a myocardial perfusion defect or an oncologist estimating the metabolic uptake of [$^{18}$F] fluorodeoxyglucose in a tumor.

Diagnostic imaging platforms and analysis tools are by definition concerned with classification (detection) tasks and have been uniformly optimized for those purposes. It should be clear that imaging biomarkers, being inherently quantitative, are concerned with either estimation tasks or combined classification/estimation tasks [47,48]. Thus, the requirements and standards for diagnostic imaging systems are somewhat different from that of imaging biomarkers. For example, the demands of image quantification and the extraction of objective image features for imaging biomarkers place strict limits on image quality that may differ from that required for diagnostic purposes, where the experience and skill of the clinician may compensate for typical nonidealities in the images. Evidently, qualitative visual image evaluation suffices for a majority of diagnostic imaging purposes. On the other hand, objective quantitative image assessment is essential for imaging biomarkers, and image acquisition and analysis systems must be optimized for this purpose. Such optimization may involve differences in hardware design, evaluation of image quality control, image reconstruction, processing and quantification methods, and software.

***Nuclear Cardiology as an Imaging Biomarker*** SPECT myocardial perfusion imaging (MPI) is a nuclear cardiology procedure developed for the clinical diagnosis of coronary artery disease [49]. The imaging procedure is based on cellular uptake of a gamma-emitting radiopharmaceutical (such as thallium-201 or various technetium-99m-labeled agents) in proportion to the regional blood flow in the myocardium [50]. The imaging procedure is typically performed twice: first, with the subject at rest, and second, after inducing hyperemia through exercise or pharmacological stress. The resulting images provide a relative measure of myocardial perfusion and allow the identification of perfusion defects. In general, perfusion defects may represent regions of possible ischemia (reversible defects) or necrotic tissue resulting from infarction (scar or fixed defects). Quantitative analysis of rest and stress images provides estimates of the perfusion defect extent and severity as well as discrimination between ischemic and scar regions [51]. In addition, numerous other quantitative measures of cardiac function can be derived when the images are acquired with electrocardiogram (ECG) gating. Such image-based measures play a critical role in guiding subsequent medical intervention and clinical management of coronary artery disease.

As a mature imaging technology, SPECT MPI has been developed and improved continuously for nearly 25 years, and apparently has many characteristics of a qualified stage 4 imaging biomarker:

- Extensive validation of image-based quantitative measures of myocardial perfusion (perfusion defect type, extent, and severity)
- Extensive clinical qualification for the diagnosis of coronary artery disease
- Standardized protocols for image acquisition and reporting
- Standardized automated image processing and quantification methods [52]
- Validated imaging hardware and software tools readily available [53]
- Cost-effective imaging procedures used widely in clinical practice

In addition to the availability of standardized image quantification, an important aspect of SPECT MPI that sets it apart from many other diagnostic imaging applications is the routine use of normal subject databases. Image-based assessment of abnormal perfusion is done by computer-automated comparison of perfusion parameters for a given patient with normal limits defined by databases of subjects with a low likelihood of coronary artery disease [51]. Moreover, the accuracy of automated assessment is comparable to human visual interpretation of the images, but with potentially lower variability [54].

Despite these characteristics and its broad acceptance in diagnostic imaging, SPECT MPI appears to have only limited utility currently as a tool for drug development. As a diagnostic tool, SPECT MPI technology and standards have been optimized for the clinical diagnostic setting. In particular, recent use of SPECT MPI for serial imaging of patients has highlighted limitations and the need for further research to optimize SPECT MPI for serial image assessment [55,56]. Furthermore, despite the availability of more objective quantitative measures of myocardial perfusion deficit, recent clinical trials that have used SPECT MPI evaluation as a primary endpoint have been compelled to use visual categorical interpretations and semiquantitative measures for drug registration [57,58]. We may speculate that these limitations are due in part to imaging systems that have been optimized for the classification task rather than the estimation task required of imaging biomarkers in drug development. For example, the quantitative thresholds that have been established for the use of normal subject databases in SPECT MPI software have generally been optimized by reference to expert visual reads in the single study setting, which may not be optimal for quantitative evaluation of serial studies. Thus, SPECT MPI technology illustrates the subtle, yet important differences between conventional diagnostic imaging and imaging biomarkers.

## Key Advantages of Imaging Biomarkers

As a tool in drug development, imaging biomarkers share several general advantages among all imaging modalities. Imaging biomarkers provide the unique ability to visualize anatomy as well as to spatially localize physiological and molecular function in vivo. Additionally, most imaging modalities have the capability to acquire repeated or temporally resolved images which allow a study of various dynamic biological processes. In vivo image-based evalua-

tion of disease processes or drug targets occurs in their respective biological microenvironments, accounting for both systemic and local modulators. As in vivo assays, imaging biomarkers also share with in vitro biomarkers the ability to determine drug–target interactions, to help optimize drug dose, and to evaluate longitudinally the response to therapy in vivo [59].

A broad range of sensitivity and spatial resolution is also available, providing great flexibility in the choice of applications. High-resolution CT and MRI anatomical imaging biomarkers can evaluate gross therapeutic effects at the level of organ systems; nuclear, CT, and MRI perfusion imaging biomarkers can probe functional effects at a regional tissue and vascular level; nuclear, MRI, and optical molecular imaging biomarkers can provide readouts down to the level of cellular and molecular effects. This range can sometimes be an advantage when considering the process of clinical qualification. For example, although molecular imaging applications may attain the level of detail necessary to test for proof of mechanism, clinical qualification of imaging biomarkers will probably be facilitated by coarser biological "resolution" at the macroscopic level of organ systems which may more readily be related to a clinical endpoint.

In addition to the clinical relevance of the various imaging modalities, there is also the possibility for translation of preclinical imaging applications to the clinic, which provides a potential for continuity of readout parameters between preclinical safety and efficacy studies in animal models and eventual clinical evaluations in humans. Furthermore, a majority of hospitals and medical centers (often, the sites participating in later-phase clinical drug trials) typically have direct access to clinical imaging centers or imaging equipment.

Longitudinal assessment of individual subjects provides a potential for reduced statistical variability, and consequently a reduction in the number of study subjects. Clearly, this can benefit drug development through faster studies and reduced costs; however, in practice, many additional factors can influence the net cost savings and efficiency achieved in using an imaging biomarker. These factors are related to the implementation of imaging biomarkers and must be evaluated carefully for each imaging biomarker application.

## Limitations of Imaging Biomarkers

There are generally three categories of imaging biomarker limitations. First, there are limitations that are likely to be addressed in the near future by the accelerating rate of imaging biomarker development. The complex and multidisciplinary nature of image acquisition hardware and analysis methods has hindered the translation of promising image-based functional measures into validated and qualified imaging biomarkers. Similarly, a lack of standardization has also impeded imaging biomarker development, since variations in methodologies, as well as hardware platforms with differing capabilities, have made it difficult to compare and evaluate potential imaging biomarkers across sites. Compared to in vitro biomarkers, it may be costly and time consuming

to acquire the clinical evidence necessary to establish a biological relationship between an imaging biomarker and a particular disease state. All of these factors have limited the introduction of imaging biomarkers into clinical practice for patient management, diminishing the incentive to commercialize such technologies. Additionally, despite the impressive preclinical accomplishments of molecular imaging to date, expansion of such applications to the clinic has been limited by the fact that relatively few molecular imaging agents have been approved for clinical use in humans [22,60].

However, these limitations are starting to be addressed by novel approaches to imaging biomarker development, broad collaborations to standardize technology, and federal initiatives to foster the development of imaging agents and increase the availability of component tools and methods. In addition, radioisotope production for some important radionuclides, such as $^{18}F$, $^{11}C$, $^{13}N$, and $^{15}O$, although complex and expensive, is beginning to be addressed by recent innovations in cyclotron technology [61].

Second, there are limitations in the underlying imaging technologies and methodologies that we might expect to be addressed by ongoing basic research and technology development already occurring independent of imaging biomarker development. The widespread diagnostic use of imaging motivates continual research and vendor improvements in hardware, software, and acquisition methods. Such improvements have recently included faster imaging and hardware improvements for MRI, innovations that reduce radiation dose in CT, new hardware designs that improve sensitivity and resolution of nuclear imaging modalities, and new capabilities afforded by combining modalities, as in SPECT/CT, PET/CT, and most recently, PET/MRI. Furthermore, many image analysis approaches and tools have been borrowed from ongoing computer vision research. All such advances have the potential to benefit imaging biomarkers' performance; however, careful attention must be paid to the differing criteria for system optimization between diagnostic and biomarker applications.

Finally, there are inherent limitations in imaging biomarkers that are not likely to be fully mitigated by future development. Within the spectrum of potential imaging biomarkers, those that rely on endogenous contrast mechanisms have the advantage of avoiding the added complexity and safety concerns introduced by the use of exogenous imaging agents. However, such image-based functional measures are often inherently nonspecific, relying on biological models in which the connection between measurement and function may not be interpreted easily or directly. In addition, there is a growing perception that the increased use of nuclear and CT modalities, which utilize ionizing radiation, presents a public health concern [62,63]. Diagnostic imaging has been guided by the principle that the risks of ionizing radiation should always be weighed against the benefits of the imaging procedure to the patient [64]; however, in some cases, radiation doses from medical tests may exceed limits known to increase the risk of cancer, particularly in the case of serial imaging [64]. Although progress has recently been made in reducing radiation

doses in CT procedures [65], the image quality of CT depends inherently on a nonnegligible radiation exposure. Additional advantages and limitations specific to different imaging modalities and methods are discussed further in a later section.

## Importance of Context: Disease, Therapeutic Strategy, Development Stage, and Alternative Approaches

The development or implementation of any particular imaging biomarker must be preceded by consideration of the current research environment, the local availability of technology and resources, and an attempt to evaluate the relative utility, efficiency, and cost-effectiveness of alternative approaches. Local implementation of an imaging biomarker is a time-consuming process, even for methods validated and published previously. Commercially available imaging systems are generally tailored toward diagnostic rather than quantitative applications, and as a consequence, the implementation of an imaging biomarker often involves applying customized acquisition, radiotracer synthesis, or analysis methods that must be locally optimized and compared to published results. In a preclinical setting, the implementation process places great demands on the local availability of resources such as MRI pulse sequences and acquisition methods, radiotracer production facilities, appropriate animal models, and image analysis tools, among many others. In a clinical research setting, an imaging biomarker may have to be implemented across multiple centers. An overriding concern in the usability of any particular imaging biomarker once implemented is the overall throughput that can be achieved [66].

Alongside these practical concerns are various scientific questions about which technique among several will be optimal. Within any one imaging biomarker application, there may be multiple methods for acquiring similar data, and multiple approaches for image reconstruction, processing, and quantification. Similarly, there may be multiple imaging or in vitro biomarkers that address the same biological function or clinical endpoint. Such choices typically have to account for incomplete data comparing the methods and limited available resources.

When considering the use of imaging biomarkers, the dominant focus is often on the technology, implementation issues, or necessary tools. Although implementation choices must be weighed carefully, it is important to emphasize that imaging biomarkers, like any other biomarker, should be specified in terms of the disease context and therapeutic strategy, as well as the development stage and questions to be answered. Defining the clinical context of a given imaging biomarker is part of the process of biomarker validation, which answers the question: What are the biological conditions, disease states, and therapies under which the use of the imaging biomarker will result in the empirically determined reliability and validity? For example, the location of a tumor may limit our ability to obtain a robust quantitative assessment of treatment effects due to excessive respiratory or cardiac motion. An imaging

biomarker that is validated and qualified for a given tumor type and therapeutic class cannot be assumed to be validated and qualified for tumors of other types or anatomical locations or other therapies without additional validation data.

Conversely, in drug development, time efficiency and the value of investing in imaging technology resources can be maximized by selecting and implementing cross-mechanism imaging biomarkers [67]. For example, multiple imaging biomarkers may share a common MRI pulse sequence or acquisition method, such as $T_2$*-weighted dynamic imaging for dynamic susceptibility contrast (DSC) bolus tracking and blood-oxygenation-level-dependent (BOLD) functional MRI, or $T_2$ mapping for measuring peripheral edema or liver iron concentration. Similarly, a custom PET radiotracer may be developed for a specific development program but may have utility in other therapeutic areas [45]. Such coordination requires significant planning and broad alignment across discovery and development groups and therapeutic areas, which may be difficult to achieve in large organizations.

## SCOPE OF IMAGING BIOMARKERS IN DRUG DEVELOPMENT

Parallel developments in our knowledge and understanding of biology and disease, and advances in biomedical technologies, have dramatically increased our ability to discover and develop new therapies as well as to evaluate the biological effects of disease interventions. Imaging technologies have played an important role across the spectrum of drug discovery and development [9,20]. Apart from basic biological research, the roles of imaging biomarkers in drug development generally fall into two categories: supporting internal decision making, and to support the demonstration of efficacy in pivotal clinical trials for registration.

Within the category of imaging biomarkers used for decision making in drug development, there are three fundamental applications that imaging biomarkers have in common with in vitro biomarker technologies: confirming that a drug candidate hits the intended biological target, testing whether hitting the target, alters the disease process (proof of mechanism), and testing whether altering the disease process affects the clinical status of the patient (proof-of-therapeutic concept) [40,45]. Imaging biomarkers have provided early critical information at each of these development stage gates through in vivo molecular imaging studies of competitive binding or receptor occupancy [45], imaging of target distribution and radiolabeled drug distribution [68,69], lead optimization, and preclinical and early clinical efficacy testing [19,70]. Other tasks in early clinical development that imaging biomarkers have addressed include appropriate dose and regimen selection and in vivo pharmacokinetic/pharmacodynamic studies [71,72], patient stratification, and study population enrichment [40].

Importantly, imaging biomarkers for internal industry decision making have demonstrated value for drug development without comprehensive vali-

dation or clinical qualification [67]. Indeed, many such biomarkers may be proprietary and specific to a particular development program, therapeutic target, or mechanism [45]. However, achieving a stage of assay validation appropriate to a given task and the associated risk is a crucial but often time-consuming process. The use of novel imaging biomarkers is most effective if development and characterization activities, such as PET radiotracer development or MRI pulse sequence and method development, are begun as early as possible and ideally in tandem with the corresponding drug development program [45].

Although imaging biomarkers have proven useful in many aspects of drug development without being fully clinically qualified, there is renewed interest from multiple stakeholders to develop qualified surrogate endpoints and expedite the lengthy and costly drug approval process [39]. In addition to the well-documented difficulties of clinical qualification [45], the potential impact of such tools for regulatory decision making will be limited unless they achieve some measure of standardization and cost-effectiveness, and become widely accepted and widely available. In the next section we examine in some detail a few of the imaging biomarkers that are currently, or are poised to become, such high-impact tools for drug development in oncology.

## PROFILES OF IMAGING BIOMARKERS FROM ONCOLOGY

### Morphological Evaluation of Tumor Response

There is a broad range of imaging biomarkers applicable to oncology drug development [59]. This spans exploratory imaging methodology that may contribute to early development decision making in small studies (e.g., DCE-MRI assessment of anti-angiogenics [73]) to robust and broadly applicable assessments of disease burden (e.g., RECIST (response evaluation criteria in solid tumors) [74]). RECIST provides a framework to use imaging (predominantly CT) to document baseline disease burden and define change over time.

It could be argued that RECIST should not be considered a biomarker since the aim of RECIST is to provide a broad categorization of response. However, the quantitative components of RECIST, the lesion size measurements, are measurable characteristics reflecting disease and response to treatment, and it therefore seems reasonable to consider it alongside other imaging biomarkers. Furthermore, understanding the attributes of RECIST will help inform the development of other imaging-derived biomarkers: (1) how it was developed; (2) how it became an international standard of assessment; (3) how it addresses the challenges of multisite application, including multiple modalities, acquisition parameters, interpreting radiologists; and (4) how it is implemented into large-scale clinical trials.

***Background*** In the early 1980s the World Health Organization (WHO) published recommendations aimed at standardizing tumor response assess-

ment [75] based on criteria formulated in 1979. The recommendations described minimum requirements for reporting response assessments using clinical, radiological, biochemical, and pathological factors. In terms of radiological assessment, this was to be performed on single or multiple lesions using a bidimensional approach to estimate tumor size. Further, clinical or radiological assessment could be used to review new lesions which would lead to disease progression irrespective of other changes. Four groups were described: complete response (CR), partial response (PR), stable disease (SD), and progressive disease (PD). This thresholding into discrete response categories was subsequently applied widely and continues to this day. Despite the longevity of this simple classification scheme it was noted early that there are significant advantages of reporting continuous tumor size estimates, "especially in the phase II setting" [76]. Although adoption of the broad principles was seen, subsequent modification based on different expert group preferences and tumor-specific requirements resulted in a heterogeneous use of the WHO criteria as described in the commentary by Michaelis and Ratain [77]. It was apparent that a new standard was required for measuring response of solid tumors in clinical trials. This was with a backdrop of dramatic change in standard imaging methodology and application (including improvements in CT, ultrasound, MRI, and PET) that offered potentially many new or improved ways in which response could be evaluated. With such a diversity of potential assessments the new criteria had to specifically address how lesion sizes needed to be estimated to avoid continual diversification of applied methodology.

A collaboration between the European Organization for Research and Treatment of Cancer, the National Cancer Institute, and the National Cancer Institute of Canada culminated in a publication of the new guidelines in 2000 [78]. The new guidelines maintained the classification scheme of CR, PR, SD, and PD but made a number of important changes: adoption of a simplified tumor size estimation (i.e., longest diameter), a definition of how many lesions (target lesions) should contribute to the size estimation, a description of how nontarget lesions should be assessed, and a description of which imaging methodologies should be considered for response assessment. RECIST has been adopted widely and continues to contribute to many endpoints in cancer clinical trials, including progression-free survival.

### *Limitations*

*Tumor-Specific Limitations* As with all such generalized criteria, there are instances when the approach becomes problematic. Since the publication of the original RECIST guidelines, many subsequent publications have detailed the limitations of applying RECIST for certain tumor types and certain therapies, such as cytostatic agents and general comparisons of RECIST with WHO [79]. The review by Therasse et al., in 2006 [80] documents the tumor-specific issues pertinent to RECIST.

It is clear that with challenges associated with different tumor types, modifications to the RECIST framework may provide benefits. Examples include the evaluation of gastrointestinal stromal tumors (GISTs) treated with imatinib. It was found that response by RECIST did not sufficiently translate into survival. However, when response was defined as a 10% reduction in tumor size or a 15% reduction in contrast-enhanced CT density, better linkage with outcome was observed [81,82]. Another example is that of mesothelioma, where Byrne and Nowak describe modifications to the RECIST criteria [83] that improve correlation with both survival and lung function.

*Limitations of Pure Radiological Assessment* RECIST offers a generalized framework for defining response in clinical trials which has been integral to many successful drug development programs. However, there are many instances where radiological evaluation alone is limited and does not typify decision making in clinical practice. Often, the clinical decision making will be based on multiple factors (such as *CA-125* for ovarian cancer), and clinical trial assessments may need to incorporate nonradiological parameters alongside radiological assessment.

*Centralized Radiological Review* One of the recommendations in the RECIST guidelines is that response assessments should be made based on independent assessment, and this is often considered a requirement for regulatory submission. Central and independent image review aims to reduce the variability of assessment and remove or reduce the potential for investigator-introduced bias. Central review of high volumes of imaging data from hundreds of sites across many countries does come with high complexity and high cost to the study sponsor. Furthermore, how do we deal with disagreements between the central reviewer and the site-based assessment? The site-based radiologist is likely to be performing RECIST differently from the central reviewer: selecting a different number of target lesions, defining the longest diameter of the lesion differently, a different judgment on nontarget lesions, and equivocal new lesions may be interpreted differently. When there is subjectivity associated with the application of criteria such as RECIST it is important to identify sources of variability associated with image interpretation such that different results from different readers can be understood.

*Unidimensional Evaluations* A frequently raised issue with RECIST and cause of discordance with WHO is the reliance on a single-dimensional size estimation. Schwartz et al. [84,85] discussed this issue in relation to esophageal cancer. With multidetector CT technology and MRI a three-dimensional lesion assessment can be performed and offers a theoretical advantage in terms of likely sensitivity to change and avoidance of lesion eccentricity problems. However, one of the most significant advantages of RECIST is the simplicity of the imaging required. If three-dimensional imaging was required

in a 100-site clinical trial, there would be many challenges to ensuring that this is done to a level that would allow robust volumetric assessments with acceptable variability. Further, the additional radiology review time (central and site based) required to outline multiple lesions on multiple slices would be substantial. It is likely that three-dimensional assessments will have a clear benefit in a number of applications, especially when deployment of a standardized three-dimensional acquisition can be achieved readily. A significant amount of data is required, however, to demonstrate that the theoretical advantages translate broadly into a measure more predictive of response and that the practical issues can be overcome for multisite clinical trials.

*Imaging Technology* The ability to define meaningful response is strongly influenced by the methodology available and the mass of data that links a method with clinical outcome. RECIST focuses on morphological assessment with CT since the technology is available across all clinical trial centers, provides a relatively consistent acquisition, and is used most widely across the majority of cancers. However, it is recognized that technologies such as FDG-PET as indicators of metabolic response could provide improved response assessments in the future. Owing to the tumor-specific utility of metabolic imaging, it is likely that approaches such as FDG-PET will become very important for some indications, but not broadly applicable. In lymphoma, for example, FDG-PET is an integral component of the current recommendations for response evaluation [86].

***Continual Development of Response Criteria*** Response criteria will need to evolve continually with imaging technologies, whether new molecular imaging approaches become available or there are broad improvements in standard morphological assessment with CT or MRI. After extensive meta-analyses and in response to changes in imaging practice since RECIST was first published, modifications were proposed in 2009 in criteria termed *RECIST 1.1* [202]. One challenge in applying the new criteria will be to ensure consistency within any a given clinical trial. Since oncology trials may often take years to complete, there will be an overlap between use of the original RECIST and the new guidelines.

***Learning from RECIST Development*** There are many important lessons to learn from the way in which RECIST has evolved to become an integral component of many clinical trials involving solid tumors:

- Developing a consensus around response criteria takes a considerable effort requiring multidisciplinary input and broad representation from stakeholders.
- Criteria should be sufficiently broad that revision from year to year is not required if, for example, imaging technologies change.

- To demonstrate a robust relationship to clinical outcome, very significant data sets are required. The new RECIST modifications use data from over 6500 subjects.
- Response criteria applicable to large multicenter trials need to be pragmatic to ensure utility across many different imaging platforms and alignment with country-specific practices and radiologist preferences.

Although RECIST may seem far removed from the concept of an imaging-biomarker it represents the most widely used imaging-based clinical trial methodology in oncology. For this reason, an understanding of how it has evolved and is deployed practically is important to consider when other techniques are being developed.

## [$^{18}$F]FDG-PET

The increased glucose metabolism associated with many cancers has been established for some time and the origin and consequences remain areas of continued discussion [87]. [$^{18}$F]fluorodeoxyglucose (FDG) PET ([$^{18}$F]FDG-PET) exploits this general phenomenon, facilitating the widespread application of a molecular imaging technique for oncology. FDG is taken in cells via glucose transporters (Glut-1), phosphorylated by hexokinase, and becomes trapped. The rate of uptake is related to glucose utilization and therefore an [$^{18}$F]FDG-PET examination interrogates the glucose uptake and subsequent metabolism. The [$^{18}$F]FDG-PET study therefore broadly defines tumor metabolic rate and is also considered to reflect viable cell fraction, although the relationship is not necessarily straightforward [88].

The extensive review by Gambhir et al. outlines the broad use of [$^{18}$F]FDG-PET for diagnosis, staging, assessing recurrence, and monitoring response [89]. It is interesting to note the varied sensitivity to detect primary cancers relative to the generally high avidity to metastases. A more recent review by Kelloff et al. [90] provides an extensive review of [$^{18}$F]FDG-PET applied to clinical practice and oncology drug development. Although the role in all tumor types is yet to be established, such reviews emphasize the high availability of [$^{18}$F]FDG-PET and broad applicability, both of which are important defining points in the role of [$^{18}$F]FDG-PET in drug development.

***Application of FDG-PET to Drug Development*** As explained by Kelloff et al. [90], current data suggest that [$^{18}$F]FDG-PET response is likely to be sufficiently predictive of clinical benefit. Such surrogacy status would broaden the impact of [$^{18}$F]FDG-PET in its ability to be used as a provider of key trial endpoints, including increased support of proof of concept through phase II studies to even the potential to provide a true surrogate endpoint for phase III studies. Although full validation studies are yet to be completed, data from some indications (NSCLC [91] and lymphoma, for example) suggest that [$^{18}$F] FDG-PET can be used successfully to define response to approved therapies

and predict endpoints such as overall survival and progression-free survival [92–94]. Sarcoma is also an indication where [$^{18}$F]FDG-PET response provides a better prediction than tumor size change of histopathological response to neoadjuvant therapy [95]. Published and ongoing studies of response with approved therapies are likely to provide a significant body of data to understand the scope of [$^{18}$F]FDG-PET-based endpoints in clinical trials of many tumor types.

With an increased understanding of [$^{18}$F]FDG-PET responses to standard chemotherapies will come an accelerated application to support the clinical development of novel therapeutics. The demonstration by Stroobants et al. [96] that PET provides an early indicator of metabolic response to imatinib mesylate for subjects with soft tissues sarcoma was a convincing example of how metabolic response can significantly precede any morphological change. Even 48 hours after beginning treatment, it was demonstrated that response could be identified in the subgroup contributing this early time point. Additional data supported the sensitivity of [$^{18}$F]FDG-PET to define treatment response in gastrointestinal stromal tumors (GISTs) [97,98]. A review of the rapidly evolving role of [$^{18}$F]FDG-PET for GISTs is given by Van den Abbeele [99], who emphasizes that the experiences with GISTs are being seen to provide more personalized assessment of response of targeted therapy.

***Method Standardization*** Consistent acquisition and analysis of [$^{18}$F]FDG-PET data within clinical trials is paramount to successful interpretation of the clinical trial data. [$^{18}$F]FDG-PET analysis can simply be undertaken by visual inspection of the PET images. Whilst commonly done in clinical practice it is often limited for clinical trials. However, there are some instances where visual inspection is considered sufficient for clinical trials such as for response criteria for lymphoma [86]. Generally, a more quantitative assessment is considered necessary for applying [$^{18}$F]FDG-PET to clinical trials. The most comprehensive quantification of FDG uptake is achieved by acquiring a dynamic scan with simultaneous assessment of tracer concentration in arterial blood. Subsequent Patlak analysis (and other methods) can yield metabolic rate constants. The dynamic scanning, arterial line, and complex analysis are not suitable for all clinical trials. The most widely used approach for [$^{18}$F]FDG-PET analysis in clinical trials is a semiquantitative approach providing the standardized uptake value (SUV). This approach simply normalizes tumor uptake to injected dose and body weight, and the acquisition procedures are favorable to a busy PET center.

In 1999 the EORTC (European Organization for Research and Treatment of Cancer) PET study group provided recommendations on how PET should be performed for studying clinical response [100]. These recommendations emphasized the need for consistent measurement, analysis, and interpretation of response. In 2006, Shankar et al. [101] provided recommendations on how [$^{18}$F]FDG-PET should be applied to study therapeutic response in National Cancer Institute trials. Other groups from both industry and academia have

defined protocol standards for clinical trials [102,103]. Other publications provide important insight into the practical issues associated with [$^{18}$F]FDG-PET in clinical trials. For example, Weber [104] describes many pitfalls of seemingly straightforward SUV analyses, including errors associated with incorrect scanner calibration and varied period between injection and imaging. Furthermore, Westerterp et al. [105] describe the impact of image processing and ROI definition procedures on the SUV analysis. It demonstrates that despite the conceptual simplicity of SUV, every attention needs to be paid to all components in the imaging chain to ensure successful measurement in a multicenter setting. Also important may be tumor-type specific nuances of the PET approach as described by Lind et al. [106], where specific technical considerations are important to optimize sensitivity to detect disease during follow-up of breast cancer.

The published recommendations and further practical insights can be used to form an [$^{18}$F]FDG-PET protocol to define unambiguously how the patient is to be prepared, how the images are to be acquired, and how the images are to be processed and reported for a given clinical trial. Although there are still multiple standards that could be adopted for [$^{18}$F]FDG-PET, the attention focused on standardization encourages wide adoption of quantitative [$^{18}$F]FDG-PET. Many investigating sites now have experience of clinical trial imaging using [$^{18}$F]FDG-PET and consistently demonstrate a willingness to follow a standard protocol. Given the varied approaches by which analysis could be performed, centralized review of PET data for SUV analysis is preferable. This is achieved either using a contract research organization with expertise in quantitative imaging or coordinated via an academic network of centers where one center takes the lead role in analysis.

In addition to SUV analyses in the study of treatment-induced change, it is important to note the use of [$^{18}$F]FDG-PET with visual interpretation for screening bone lesions, where it may have sensitivity advantages over bone scintigraphy [107]. Such bone lesion screening remains important for assessments of disease burden in many clinical studies. In some instances it may replace the need for scintigraphy where whole-body [$^{18}$F]FDG-PET is undertaken as a matter of routine. However, given the high cost of PET relative to bone scintigraphy, it remains uncertain what the role of [$^{18}$F]FDG-PET will ultimately be in this setting.

***New Tracers*** Whereas [$^{18}$F]FDG-PET remains a developing tool in terms of its role in oncology drug development, PET has the potential to do much more [108]. Specifically, FDG has significant limitations in a number of settings. Kelloff et al. [109] review the extensive array of molecular imaging probes able to define molecular targets and understand processes to support oncology drug development. The tracers in development (including probes for SPECT) facilitate the study of proliferation, apoptosis, hypoxia, and angiogenesis and can study androgen and estrogen receptors. These molecular imaging platforms will provide an array of tools applicable for different stages of drug development, including:

1. *Biodistribution and in vivo concentration.* Studies of radiolabeled drugs to interrogate in vivo concentration and distribution [110], in particular the concept of microdosing where subtherapeutic doses of labeled drugs can be given, hold great promise [111].
2. *Receptor analyses.* Understanding receptors pertinent to cancer growth continues to be of interest, particularly receptors highly relevant to therapeutic intervention (e.g., estrogen; see Katzenellenbogen et al. [112], and for *HER2* expression, [113]). In a review by Mankoff et al. [114] the potential of tumor receptor imaging is reviewed with an emphasis on the complementary role that imaging can play vis-à-vis biopsy by studying receptor expression heterogeneity.
3. *Proliferation.* Labeled thymidine analogs offer a route to noninvasive assessment of tumor proliferation [115]. Of the potential agents, [$^{18}$F]FLT (3′-deoxy-3′-fluorothymidine) has been established as a suitable agent for wide use [116]. Reports have demonstrated the key advantages of [$^{18}$F]FLT-PET over [$^{18}$F]FDG-PET in a number of tumor types [117–119]. The role of [$^{18}$F]FLT-PET continues to grow, and increased availability of the tracer is likely to further establish the technique within clinical drug development.
4. *Apoptosis.* A noninvasive probe of apoptosis would undoubtedly provide general insight into early therapeutic success both for clinical assessments and for drug development decision making. Annexin-V has received considerable attention as an apoptosis probe labeled with either $^{18}$F [120] or $^{124}$I [121]. Different approaches to measure apoptosis are also in development, as described in the review of apoptosis tracer labeling strategies by Lahorte et al. [122]. It is a clear that a robust apoptosis imaging agent will play an important role in clinical drug development.
5. *Angiogenesis.* The specificity and sensitivity of currently available surrogates of angiogenic activity (e.g., dynamic contrast-enhanced MRI) are limited. PET tracers targeting receptors up-regulated with angiogenesis, such as the integrin $\alpha_v\beta_3$, make attractive approaches to a study of angiogenesis [123] with close linkage to the tumor biology. Such agents are currently in clinical development [124,125] for cancer imaging and can be used for quantitative assessment of integrin levels in tumors [126]. Given the preponderance of antiangiogenic targets in different stages of clinical development, PET tracers able to study change in this process remain highly attractive.

The diversity of labeling strategies means that many drugs and additional tracers will become available to complement the already developing array of PET tracers. Some of these agents are clearly broadly applicable (such as proliferation and apoptosis) and could follow the route that [$^{18}$F]FDG-PET has followed: to wide clinical and drug development use. The cost–benefit

relationship of such agents is clear. Tracer development for specific drug programs (e.g., labeling a drug for biodistribution studies) may be costly in terms of finance, time, and resource, but if the biodistribution analysis identifies an important safety signal, for example, the investment is likely to be rewarding. Molecular imaging development with required multidisciplinary teams and substantial infrastructure remains a costly endeavor. However, relative to potentially late-failing drug development programs the investment can be justified in many instances.

## Dynamic Contrast-Enhanced MRI

Dynamic contrast-enhanced MRI (DCE-MRI) is a functional imaging technique performed by rapidly acquiring multiple $T_1$-weighted MR images from a given tissue during injection of a paramagnetic contrast agent. The consequential tissue signal changes are quantified, and parameters with biological linkage are extracted. A review of the experiment with a focus on the analysis required is given by Parker and Padhani [127]. Further, standardized terminology and definitions of DCE-MRI-derived parameters have been defined by Tofts et al. [128]. Parameters typically extracted and used in the study of pharmacological response include:

- $K^{\text{trans}}$ ($\text{min}^{-1}$): the volume transfer constant between plasma and the extravascular extracellular space. The parameter is related to both flow and vascular permeability and, as such, change cannot be interpreted precisely. However, successful pharmacological intervention is expected to reduce this parameter by either flow and/or permeability change.
- $v_e$ (unitless): the volume fraction of the extravascular extracellular space. This is assumed to relate to interstitial space, although the relationship remains complex and posttreatment changes are not predictable.
- $k_{\text{ep}}$ ($\text{min}^{-1}$): the rate constant between the extravascular extracellular space and the plasma.
- IAUC: the initial area under the curve, typically over the first 60s. This is a semiquantitative expression of the initial contrast enhancement, which requires no data modeling. The relationship to physiology is complex [129], although both flow and permeability are likely to affect the parameter, and successful antiangiogenic treatment is expected to reduce the value.

In the recommendations by Leach et al. [130] both $K^{\text{trans}}$ and IAUC should be used as primary DCE-MRI endpoints, with $v_e$ and $k_{\text{ep}}$ as secondary endpoints.

As emphasized in the review by O'Connor et al. [131], DCE-MRI has been used widely for the study of angiogenesis inhibitors. Since this class of agents has received considerable attention across industry, interest in DCE-MRI has

become widespread. The review by Jayson and Waterton [132] outlines the progress in use of the technique for drug development, focusing on fundamental aspects such as design of the protocol, measurement validity, and reproducibility. Work focusing on DCE-MRI as a pharmacodynamic endpoint has been complemented by developing our understanding of the technique for more routine clinical use: for prognostication, for example.

The use of DCE-MRI offers significant advantages over other methods able to interrogate aspects of tissue vascularity. With careful implementation, multisite standardization can be achieved and sufficient reproducibility relative to typical pharmacodynamic effects can be realized. However, it could be argued that angiogenesis inhibitors either currently in development or marketed may have proceeded without DCE-MRI within the development program. So what does DCE-MRI add to the development paradigm, and why, if such a localized indicator of antiangiogenic activity exists does it not form a fundamental step in the development of such agents? First, there are technical challenges to successful implementation that form impediments to broader use. Second, there is still insufficient understanding of the relationship between given DCE-MRI parameters and both histopathology and clinical outcome. These uncertainties lead to difficulties in interpreting DCE-MRI studies. For example, how much of a change in a DCE-MRI parameter is enough to predict benefit?

### *Method Standardization and Deployment Challenges*

*Site Limitations* DCE-MRI remains a specialized technique with limited routine application, and therefore many radiology departments will have limited experience with its use. It is important to consider the practicalities of consistent DCE-MRI implementation across multiple sites required for a given clinical trial. The first step requiring consideration is the selection of sites capable of performing DCE-MRI by adhering to a common acquisition for the study. One factor to consider is what experience site personnel have in performing DCE-MRI. However, this is not to say that sites with few experienced personnel are not capable of undertaking DCE-MRI, but the users must be committed to adhering to a prescribed protocol.

Statistically, it may be better to have fewer subjects scanned at a small number of sites where the imaging can be tightly controlled versus many sites with greater diversity of equipment and experience. A pharmaceutical company considering multiple studies could consider developing a network of specialized imaging sites able to perform consistent imaging and where good communication between sites can help optimize imaging.

*Implementing DCE-MRI Within the Clinical Protocol* A great variety of options exist regarding incorporating DCE-MRI within the clinical protocol. Some of the most important factors to consider are:

- Is a repeat baseline examination necessary to establish methodological reproducibility?
- When should posttherapeutic administration imaging be performed?
- What are the primary DCE-MRI endpoints?

These questions should be answered by considering what is known about the expected pharmacology of the drug and what has been done previously with similar agents. Important practical parameters include how many examinations will be acceptable to the subject (with a careful review of other required procedures) and whether close time points present scheduling challenges to the radiology department.

It has been recommended that reproducibility examinations be built into the study where possible in the form of a repeat baseline [130]. This would typically be done by performing two examinations within a week prior to beginning of therapy. An example of analysis of a repeat baseline study includes that by Galbraith et al. [133], where repeat examinations performed one week apart provided confidence intervals for $K^{trans}$ and $IAUC_{90}$ (64% and 61%, respectively). Other examples include that by Roberts et al. [134], where investigators assessed repeat examinations from data across two centers in multiple tumor types, comparing compartmental modeling versus model-free analysis. The 95% confidence intervals for $K^{trans}$ and $IAUC_{60}$ were calculated to be 35% and 55%, respectively. Clear differences in the reproducibility are apparent from the published examples and are expected to arise from differences in acquisition, modeling techniques, and assumptions in the model. This gives credence to the idea that a reproducibility assessment is often important, and that if performed it must be representative of subsequent study conditions. Although changes following administration of drug are often large relative to the methodological variability, in many instances it may be important to minimize the variability as much as possible. In a publication by Parker et al. [135] it is demonstrated that significant improvement in reproducibility of $K^{trans}$ and other parameters can be attained by using a population-based arterial input function. Such improvements in reproducibility are likely to be important. In a study where dose is varied, using DCE-MRI to understanding the lower limit of biological effectiveness could be important, and the measurement reproducibility will have a direct impact on the ability to define subtle change at low doses.

Published DCE-MRI studies show a range of selected posttherapy measurement time points [131]. Between different drugs there will be significant dosing differences, pharmacokinetic properties, and differences in mechanism likely to lead to varied time scales of DCE-MRI response. Therefore, there is no consistent formula to select posttreatment time points. However, where studies do include an early time point (such as one or two days after therapy has begun), a large response is generally seen and is similar in magnitude to subsequent time points. The data by Morgan et al. [136], Mross et al. [137], and Thomas et al. [138] emphasize the early response (day 2) that can be

measured consistently between studies, which then persists (out to day 28). It would thus seem that in most instances an early time point provides significant data to evaluate vascular response.

*Choosing a Standardized Protocol* A number of acquisition and analysis options exist to perform DCE-MRI. For any one study, consistent application for patients being investigated is an obvious requirement to keep variability minimized. However, for a given company there are clear benefits in maintaining a consistent acquisition and analysis protocol across multiple studies: reduced operational burden to develop acquisition guidelines and the ability to compare one study to the next potentially to compare the magnitude of response between different drugs, doses, or dosing schedules. There are also benefits to developing consistent practices for both academic- and industry-sponsored DCE-MRI-based studies:

- Increased awareness of a standard protocol to minimize the complexity encountered by radiology departments in dealing with many different DCE-MRI protocols for different studies.
- Potential to perform metaanalyses on data from multiple studies to query relationships between DCE-MRI response and clinical outcome.

Leach et al., on behalf of Cancer Research UK, proposed recommendations for performing DCE-MRI for studying antiangiogenic and antivascular therapies [130]. Their technique provides an academic and industry perspective on the key attributes of a standardized DCE-MRI acquisition. Owing to the differences in the way the technique is implemented by different scanners, different acquisition protocols will often be required from one center to the next. However, provided that cross-site implementation is undertaken carefully, a DCE-MRI measurement at one center should be comparable with that taken at another.

MRI technology changes at a significant pace, evidenced by multichannel technology and availability of scanners operating at static magnetic field strengths of 3T and above. Standardizing measurements from one study to the next is a challenge with a background of technological evolution. When a new technology (e.g., 3T MRI) is introduced, a careful comparison with existing technology is required to ensure equivalence of measurement.

*Responsibilities for Deployment and Centralized Analysis* Ideally, multiple sites with quantitative imaging expertise will be selectable to ensure that significant recruitment goals can be achieved in a reasonable period of time. Often, this may not be the case, and sites with limited imaging experience are required. For this reason, deployment of the DCE-MRI acquisition is complex, costly, and time consuming, requiring the following activities: review of the adequacy of scanner specifications, implementation of the MRI sequences required, scanner performance evaluation, training of site technologists,

instructions to upload the data in a timely manner on scan completion, robust quality control steps, and centralized analysis. Often, a third-party company, typically a contract research organization with imaging expertise, can be given responsibility for these activities. Alternatively, one clinical site in a network can be responsible for defining the acquisition protocol and communicating imaging details with partnering sites. The latter is particularly applicable where all sites have expertise in quantitative imaging. Whatever the approach selected, it is important that data acquired be transported readily (ideally via electronic transfer) to a central analysis lab in order that any important deviations from the acquisition protocol can be identified to ensure future consistency.

Owing to the diversity of software platforms able to analyze DCE-MRI and the options available for analysis, it is imperative that data sets be reviewed centrally using a consistent process. This will ensure that variability in the analysis is kept to an absolute minimum. Typically, each analyzable lesion has an associated DCE-MRI parameter created ($K^{trans}$, IAUC, and others) following pixel-by-pixel analysis. A mean value associated with each lesion is typically assumed to provide the simplest output with more advanced analysis (such as heterogeneity analyses) potentially able to provide further insight into the data.

*Toxicity of Gadolinium-Based Contrast Agents* Data show that administration of gadolinium-based contrast media is associated with a risk of developing nephrogenic systemic fibrosis (NSF) [139–141]. Although understanding is still limited, it appears that risk factors for NSF include reduced kidney function; multiple exposures to gadolinium-based chelates; the use of linear chelates, indicating a potential relationship to thermodynamic stability [142]; and the presence of major tissue injury, termed *pro-inflammatory conditions* [143].

It is clear that much is still to be understood about NSF and risk factors involved. However, it is prudent to minimize the risk of NSF for all subjects being exposed to gadolinium as part of a DCE-MRI examination or other MRI study based on existing data. DCE-MRI studies used for drug development differ from clinical practice and should approach the issue with particular caution, owing to the following factors:

- The need for multiple injections of gadolinium-based contrast agents within a short period of time, particularly if a repeat baseline and early posttreatment follow-up is required.
- For clinical diagnostic purposes the justification of gadolinium in high-risk subjects can be clearly defined, but for a patient in a clinical drug study the benefits of receiving multiple examinations are less clear.

The safety of the patient is paramount at the same time as acquisition of data to assist the development of novel therapies remains important. A conservative approach is recommended to minimize risk. This could include:

- Minimizing the number of DCE-MRI examinations while still being able to provide an understanding of the pharmacology
- Use of a single-dose gadolinium agent
- Careful monitoring of renal function and setting boundaries below which subjects should not be studied
- Use of contrast agents that, based on current data, appear to have the lowest association with NSF
- Continual review of emerging data with necessary regular revision of guidelines

***DCE-MRI for Drug Development Decision Making*** As reviewed by O'Connor et al. [131] DCE-MRI has been used extensively to study multiple antiangiogenic and antivascular therapeutics. Many of the DCE-MRI experiments performed to date have been undertaken on drugs still in development. DCE-MRI certainly appears to be a methodology applied consistently within antiangiogenic development programs. Examples include the evaluation of AG-013736 by Liu et al. [144], where a relationship was observed between drug exposure and change in both $K^{trans}$ and IAUC from baseline to day 2. DCE-MRI was also incorporated into phase I investigations of the kinase inhibitor (VEGFR, PDGFR, FGFR) BIBF 1120 [145,146]. Both studies reported DCE-MRI findings after baseline, early (2 days [145] and 3 days [146]), and later time points (28 days [145] and 30 days [146]). Although DCE-MRI was obtained at multiple drug doses, it is not clear whether there was any dose–response relationship to support a dose decision for future studies.

A methodology able to define dose versus vascular response for antiangiogenic therapies should in theory play a significant role in many drug development programs. There do remain, however, a number of significant challenges. First, most published studies where DCE-MRI has been applied to novel therapies have been undertaken on subjects with a range of tumor types, typical of the phase I setting. This creates methodological challenges likely to add to measurement variability (and measurement failure in a percentage of patients), and biological response will be less uniform than a study of a given tumor type. Another challenge is interpretation of data. How much of a change in $K^{trans}$ is sufficient to predict subsequent treatment success? Without data linking DCE-MRI parameter change with metrics of clinical outcome in large studies, with different tumor types, and different therapies, it is not possible to establish a broad threshold of, say, the $K^{trans}$ change required to predict therapeutic success. If this could be realized, a firm understanding of radiological effectiveness from DCE-MRI could be used to inform dose decisions for a drug development program. Until such data are available, DCE-MRI is likely to be used as a supportive function contributing at least to dose decisions, evaluating early signals of efficacy, and understanding scheduling. The value that DCE-MRI brings, however, would increase significantly, and

implementation cost would clearly be justified if there were greater understanding of different levels of DCE-MRI response.

Collins [147] has critiqued how imaging (both PET and MRI) contributed to decision making in the development of combretastatin A4 phosphate. Such analyses are important in order to understand how imaging has actually contributed to decision making, the many instances when it has not, and what can be done to enhance the role of imaging in clinical drug development.

***Future Improvements in the Use of DCE-MRI*** As described previously, published recommendations will help to encourage consistent DCE-MRI measurements. These should enable pharmaceutical companies and academic groups to focus on the challenges of drug development over methodological optimization. However, the current recommendations that exist remain appropriately broad since they require applicability to scanners from different manufacturers. Greater harmonization of methods between scanner manufacturers would considerably benefit the DCE-MRI experiment, lowering the barrier to implementation and enabling broader use in drug development.

Increased standards of measurement would deliver more studies that could be subjected to metaanalysis: for example, to study DCE-MRI response versus outcome. With such relationships understood, the role of DCE-MRI in early drug development can potentially move from an interesting secondary objective to delivering primary study goals.

Clinical trials are also likely to benefit increasingly from the multiparameter assessments possible within a single MR scan session. In a study of the pan-VEGF receptor tyrosine kinase inhibitor AZD2171 in glioblastoma patients, Batchelor et al. [148] demonstrated that an extensive MRI evaluation provides significant benefit over DCE-MRI alone. The study incorporated lesion volume and apparent diffusion coefficient measurements, together with DCE-MRI-derived indices, including $K^{trans}$ and relative vessel size estimations. Such approaches are likely to be necessary to fully interpret the complex changes occurring following antiangiogenic therapy and to promote understanding of drug scheduling and how optimally to combine different therapies. Improved standardization will both enhance the ability to incorporate DCE-MRI into drug development and promote understanding of how different DCE-MRI response levels are interpreted.

## Apparent Diffusion Coefficient MRI

A number of other image-based functional measures are being investigated as potential imaging biomarkers in ongoing exploratory research. Here we briefly highlight one additional cancer application. Diffusion MRI is an image-based method used to measure the molecular diffusion of water molecules in biological tissues, and derives from the well-established NMR method of

molecular diffusion measurement [149]. The parameter measured, the apparent diffusion coefficient (ADC), reflects the diffusivity or mobility of water molecules and is termed *apparent* because of the undetermined effects of perfusion, multiple tissue water compartments, restricted diffusion due to cellular and extracellular structures, and tissue anisotropy [149].

Measurement of tissue water diffusion has proven to be remarkably versatile for characterizing tissue structure, as well as tissue changes due to pathology or the effects of therapy. Diffusion MRI has been well studied in the clinical evaluation of ischemic stroke [150]. In oncology, the application of diffusion MRI has focused on the image-based measurement of tumor ADC to detect early changes associated with treatment response [151]. ADC-MRI has been applied with some preliminary success in preclinical and clinical research as an imaging biomarker of treatment response in cancers of the brain [152,153], head and neck [154], cervix [155], breast [156], and prostate [157]. A related MRI technique, diffusion tensor imaging (DTI), has been used for noninvasive characterization of tissue anisotropy, structural integrity, and connectivity in myocardium [158] and white matter tracts in the brain [159]. In particular, the latter application has been useful in preoperative planning for brain tumor patients [160].

The concept of using ADC-MRI to evaluate the effects of therapy in solid tumors is based on the general observation of an increase in tumor ADC after cytotoxic treatments in several tumor types [161–163]. Lyng et al. [163] demonstrated in four different melanoma xenograft models that tumor ADC is inversely proportional to viable tissue cell density. It is thought that an increase in tumor ADC upon treatment reflects the development of necrosis through increased cell membrane permeability and extracellular fraction, and decreased cellularity which ultimately results in greater water mobility [164]. In some tumor types such as intracranial gliomas, an early transient decrease in ADC has also been observed prior to subsequent ADC elevation, which may be due to treatment-induced cellular swelling [152,165]. These changes generally precede gross tumor regression, so that changes in tumor ADC appear to predict such regression.

ADC-MRI offers some key advantages as a potential imaging biomarker of tumor treatment response. ADC-MRI does not require the injection of exogenous contrast agents, since it relies on the endogenous contrast mechanism of water diffusion. In addition, as an MRI-based method it does not involve exposure to ionizing radiation. Moreover, the ADC is an absolute biophysical quantity which, in principle, should be comparable across MRI hardware platforms. However, varying acquisition methodologies currently lead to some variability across hardware platforms and between different imaging centers, which could be addressed through better standardization of acquisition and processing protocols.

A primary limitation currently with ADC-MRI is the enhanced sensitivity of diffusion MRI to patient motion, such that involuntary or unrelated physiological motion can produce quantitative artifacts. A variety of acquisition

and image-processing techniques have been devised to correct or minimize such image artifacts (e.g., [165–167]), which must be addressed and optimized in the process of standardizing the imaging protocol. An additional concern is the fact that tumor ADC response to therapy can also reflect formation of edema secondary to treatment [151]. Recently developed voxel-based statistical classification approaches have improved the robustness of ADC-MRI against such potentially confounding factors [152,153]. Although ADC-MRI appears to be a promising imaging biomarker for oncology treatment monitoring, further clinical studies are needed to fully characterize the validity and reliability of ADC-MRI for different tumor types and therapeutic classes, as well as to compare the relative value of ADC-MRI with similar measures of tumor viability, such as FDG-PET.

## Selecting the Right Technique

Very often, similar measurements of biological and disease processes are provided by multiple imaging modalities or even distinct approaches within a single modality. In selecting the right technique for a given problem, it is important to consider the range of possible biomarkers (both imaging and nonimaging), as well as the varying technical requirements and available resources, any significant differences between hardware platforms, and the limitations of specific modalities. Here we illustrate the considerations for selecting a particular imaging biomarker for the problem of assessing tumor vascularity.

***Example: Studying Aspects of Tissue Vascularity*** Let us assume that we wish to evaluate the tumor response to a new antiangiogenic agent for the purposes of defining the lower limit of biological effectiveness across a dose range. What parameters need consideration when deciding on the appropriate methodology?

The advantages and disadvantages of techniques are seldom reviewed comprehensively, and more specifically, there are few studies actually comparing methodologies for their potential to study therapy. De Langen et al. provide an insightful comparison of $[^{15}O]H_2O$-PET versus DCE-MRI for tumor blood flow measurements [168]. The review focuses on both the practical aspects of the two techniques and the ability of the different techniques to probe flow. The conclusion from the comparison is that both approaches are viable methods for the study of flow, yet important differences need to be considered for each study. Goh and Padhani compare the merits of DCE-CT versus DCE-MRI in the study of tumor angiogenesis [169]. Again, it is concluded that both techniques should be considered, but a number of factors should determine selection, including drug mechanism of action, tumor location, patient characteristics, and available infrastructure and expertise [169].

The potential techniques able to define tumor vascular characteristics include the following:

*Dynamic Contrast-Enhanced CT*

- *Endpoints.* DCE-CT can measure blood flow, blood volume, permeability, and mean transit time.
- *Tumor localization.* Multidetector CT technology enables a significant coverage of the tumor during the dynamic assessment, overcoming previous limitations of the approach. Furthermore, CT offers some key advantages when imaging certain anatomical regions, as summarized by Goh and Padhani [169].
- *Clinical trial practicalities.* The technique is widely available, although it is preferable that sites have previous expertise in dynamic CT. However, training imaging centers with a standard protocol is achievable. Also, since CT is generally required for RECIST assessment of disease burden, the use of CT for a pharmacodynamic investigation may result in fewer scanning sessions.
- *Risks.* Dynamic CT may add a significant radiation dose burden that may become problematic in many patient populations. This is particularly true if these subjects are already receiving regular CT scans for standard radiological assessment, perhaps also with nuclear medicine investigations accumulating a significant dose. This is likely to limit the number of time points that are measurable within a short clinical trial, particularly compared to DCE-MRI and microbubble ultrasound.
- *Quantification.* The straightforward relationship between CT contrast agent concentration and tissue enhancement is often cited as a significant advantage that DCE-CT has over DCE-MRI, making absolute quantification of perfusion achievable. For analysis, the availability of commercial software on the scanning platform holds a significant advantage relative to other methods, although centralized analysis is often required anyway, so this advantage may be limited.

In summary, DCE-CT is a widely available, robust methodology for providing perfusion quantification [170]. However, the associated radiation dose is likely to limit the use of CT in certain patient populations and certainly keep the number of time points low.

*Dynamic Contrast-Enhanced MRI*

- *Endpoints.* DCE-MRI typically provides indices relating to permeability and flow ($K^{\text{trans}}$ and IAUC) in addition to indices relating to the tissue microenvironment ($v_e$).
- *Tumor localization.* The localization can be similar to CT in that a single level is typically scanned using multiple slices. However, coronal scanning, for example, may facilitate greater coverage if multiple lesions

require measurement. Compared to DCE-CT, DCE-MRI is not optimal for all lesions and may often suffer from artifacts rendering measurement impossible (e.g., in the mediastinum).

- *Clinical trial practicalities.* The equipment required to perform DCE-MRI is widely available, yet the expertise in quantitative MRI measurement is limited. This can often be overcome by working closely with the imaging center and providing rapid feedback on data generated. In many instances, willingness of a site to adhere to a consistent imaging protocol is preferable to a site with extensive experience, insisting that the measurement be performed a particular way. The number of time points available from DCE-MRI is one advantage, with many publications demonstrating five measurements or more are feasible. However, recent concerns regarding NSF are likely to limit the number of time points, especially in patient populations with compromised renal function.
- *Risks.* The only significant risk to the subject is from the exposure to gadolinium-containing contrast media. These risks can be minimized, but in patient populations with compromised renal function an alternative imaging technique may be deemed appropriate.
- *Quantification.* With the lack of consistent and widely available image analysis platforms for DCE-MRI, central analysis of multicenter data is paramount. A significant limitation is the inability to define flow separately from permeability. Although $K^{trans}$ and IAUC may provide useful general indicators of vascular pharmacology, interpretation can be challenging.

Without the radiation dose burden and the ability to perform multiple post-therapy time points, DCE-MRI remains attractive for many studies. However, the challenge to implement across multiple centers with the associated cost and time should not be overlooked. Furthermore, ambiguity of the imaging parameters needs to be considered carefully to ensure that DCE-MRI will contribute sufficient insight into the pharmacology.

### *Microbubble Ultrasound*

- *Endpoints.* The reported endpoints are varied and include parameters such as area under the enhancement curve, arrival time, time to peak enhancement, and counting of identified vessels.
- *Tumor localization.* Bone and air attenuation sets significant limits on accessibility of this technique to some lesions. This is a fundamental limitation that should be considered when establishing the appropriate patient population to study.
- *Clinical trial practicalities.* Ultrasound remains widely available, although centers experienced in quantitative microbubble techniques remain limited. Furthermore, differences in techniques at those centers need

harmonizing before a clinical trial can begin. Several repeat measurements are possible [171]. This could allow studies in multiple lesions or repeat measurement in the event of failure or repeated measurements averaged to minimize variability. The technique is likely to be favorable to the patient, requiring relatively quick examination times, and comfort during the examination is likely to be high. The low cost may also be an important factor, and if implemented appropriately would constitute only a small fraction of a total study budget. A frequently quoted criticism of quantitative ultrasound is the operator dependence of the measurement. However, it has been shown that with careful implementation, such dependence can be controlled [172]. How this would translate into large multicenter studies, however, is yet to be established.

- *Risks.* No significant risks are expected with repeated microbubble ultrasound investigations. Microbubble contrast media are considered generally safe, with serious adverse events rarely observed [173].
- *Quantification.* Analysis is currently limited to empirical analyses of the microbubble dynamics. As such, there is likely to be significant variability of measurement from one scanner to the next where different performance characteristics and software implementations will affect measurement. A cross-site calibration exercise combined with central analysis could overcome many of the limitations. Understanding the relationship of the ultrasound parameters to the biology may be challenging.

Microbubble ultrasound remains a quick, low-cost, highly accessible methodology for gauging vascular change [174]. Further understanding is needed of the multisite performance together with more insight into the biological linkage. For single or small multisite studies it could provide a useful method to enable many repeat measurements over a short period of time to understand relationships between pharmacokinetics and pharmacodynamic response.

### *[$^{15}$O]$H_2O$-PET*

- *Endpoints.* Flow and distribution volume are typically derived. Since the tracer is rapidly diffusible, permeability is not extracted.
- *Tumor localization.* The poor spatial resolution of PET will limit the study of small lesions. Even if such lesions are identifiable, partial volume effects are likely to make robust quantification challenging [175]. Careful screening of subjects is required to ensure that there exist, for example, at least 2-cm lesions prior to entering into the study.
- *Clinical trial practicalities.* Owing to the short half-life of $^{15}$O (2 minutes), an onsite cyclotron is required to generate the tracer and facilitate rapid administration. Even sites with a cyclotron may not produce [$^{15}$O]$H_2O$

routinely. If this technique is required at multiple sites, the infrastructure and expertise of potential sites must be assessed carefully. One benefit of the short half-life is that repeat examinations can be performed within 10 minutes of each other. This allows either repeat perfusion assessments early after therapy or use of correlative imaging such as [$^{18}$F]FDG-PET without interference. Since an arterial input function needs to be defined for quantification, rapid arterial blood sampling is required during the study. This adds significant complexity onto an imaging examination, and the practicalities need consideration when selecting this technique.

- *Risks.* Although the effective radiation dose is lower than an extensive CT scan or an [$^{18}$F]FDG-PET scan, the additional radiation dose this brings to a subject who has been scanned extensively should be considered carefully. This is particularly true where there may be no direct benefit to the subject of such a pharmacodynamic endpoint versus a diagnostic CT or PET scan.
- *Quantification.* A significant body of work exists on quantification of dynamic PET data, particularly from the brain and heart. Adaptation of such analyses can facilitate robust measurement of tumor pathophysiology [176]. Owing to different implementation options, central analysis is required if data are obtained from multiple centers.

PET provides a robust technique to quantify absolute tumor perfusion, and the quantification has many advantages over other methodologies. However, the limited availability across sites, the relatively complex patient setup, and limited performance in small lesions need careful consideration.

As outlined above, there exist many practical and basic differences between measurement techniques able to study different aspects of the same phenomenon. All decisions will be dependent on the study question being asked. For example, if analysis of lung tumor perfusion across multiple centers is required, DCE-CT is likely to be an appropriate technology. If multiple time points are required to assess relative vascular change of liver lesions, microbubble ultrasound may be an appropriate methodology.

The following parameters will define the appropriateness of the various techniques: the ability to perform centralized analysis; the patient characteristics (radiation dose considerations and sensitivity to both MR and CT contrast media), the number of subjects and study centers required for delivery of the primary study endpoint, the number of time points required to fully assess the pharmacodynamics, the drug mechanism, and the probable importance of perfusion analysis versus a measure also sensitive to permeability.

There is no single technique ideally suited to address all questions in all types of clinical trials. DCE-MRI has tended to receive considerable attention for studies of anti-angiogenics. This is probably because although it has

limitations in terms of the quantification, it comes with high-resolution robust measurement in a variety of tumor types, and multiple repeat measurements are possible in most patient populations. Despite these advantages, the limitations of DCE-MRI should be evaluated and all measurement options considered.

## THE ONGOING CHALLENGE OF IMAGING STANDARDIZATION

Without standardization of imaging methods, the variety of imaging practices, tracers, equipment, and interpretation would lead to variability far greater than any drug-induced change. Since the extent of the drug-induced change is generally unknown before the experiment, study setup should aim to minimize measurement variability as far as practically possible.

Standardization of imaging is required at a number of levels:

1. *Clinical protocol.* The clinical protocol defines how the imaging endpoint is incorporated into the clinical protocol. For example, when are imaging time points relative to drug dosing? What size lesions are expected to be measurable by the technique chosen? Consistency of how imaging is incorporated is certainly required within any drug development program to ensure that cross-comparison of studies can be made.
2. *Technique selection.* What technique is chosen to deliver a given endpoint? Deciding what techniques would generally be used for a given drug development program or throughout a development organization would aid consistency of decision making and, through familiarization, lower implementation costs and resource requirements.
3. *Patient preparation.* Standardization of patient preparation for an imaging examination includes management within the scanner: fasting requirements, patient position, and cannulation. Patient preparation is particularly important for metabolic imaging (e.g., [$^{18}$F]FDG-PET) and functional imaging (e.g., DCE-CT), where multiple factors can significantly impact the imaging result (e.g., via modulation of blood glucose level or liver blood flow).
4. *Scanner setup.* How the imaging technique is implemented on a given scanner and how this is done between different scanners at different institutions defines the most significant complexity of multisite imaging. The variety of equipment is growing as manufacturers offer more hardware and software options. This diversification increases the demands to set up imaging between two different scanners with equivalence.
5. *Image analysis and reporting.* Generally, the software platforms used by centers (on the scanner, third-party, or site proprietary) are so diverse that data must be analyzed centrally. When this is done, standardization within a study and between studies can readily be controlled.

### Unique Challenges to Standardized Imaging

The diversity of imaging hardware creates one of the most significant sources of measurement variability. Seemingly equivalent imaging methods deployed on two different scanners may provide equivalent diagnostic information and images of similar appearance. However, for quantitative imaging where imaging-derived biomarkers are required, very significant differences in derived values can occur. Also, there may exist proprietary algorithms for image reconstruction or subsequent analysis, the details of which are not known and therefore cannot be compensated for.

When implementing complex imaging across multiple centers, expert resources are required to (1) compile a site-specific imaging protocol (e.g., detail acquisition requirements for a given manufacturer), (2) provide training to the relevant site staff likely to undertake the imaging (technologist and radiologist), (3) send standard phantoms to sites and review data to ensure expected performance and equivalence between sites, (4) ensure that data are received rapidly, preferably via electronic image transfer, so that the data can be reviewed rapidly and feedback given on issues, and (5) analyze the data and provide the imaging endpoints to the sponsor for statistical analysis.

### Achieving Protocol Consensus by Relevant Stakeholders

An effective method to provide consistent imaging biomarker application is to develop an agreed protocol between experts internationally. Examples of this include DCE-MRI and [$^{18}$F]FDG-PET [101,130]. Development of such recommendations is challenging to achieve given the complexity and likely disagreement on certain components during rapid evolution of imaging technology. Such efforts tend to result in general principles that are sufficiently flexible to work across many centers and ensure that similar endpoints are reported out from different studies.

### How Much Standardization Is Enough?

The degree of standardization needs to be considered for each technique requiring deployment. Standardization also comes at a cost in terms of resource and time in particular. There should be realistic expectations that imaging cannot, for example, be comprehensively standardized at 50 centers to the extent that it can be controlled at three centers. Some imaging techniques (e.g., [$^{18}$F]FDG-PET) can be standardized by a well-considered imaging protocol likely to be adhered to by the site imaging experts. However, complex MRI methodologies may require phantoms to be shipped to all participating sites and phantom data submitted for central review prior to any patients being scanned. If budget is limited, it may be preferable to perform consistent imaging on fewer subjects at a small number of centers rather than acquiring data from more subjects without investing in standardization.

It is important to remember that standardization is never likely to be achieved completely. With the rapid developments in imaging hardware, radiology best practice and contrast media/tracers standardization need to adapt. For example, with the increasing availability of 3T MRI scanners relative to the standard 1.5T scanner, when should 3T be recommended? A reasonable approach is that where data support the use of new hardware for a given application, equivalence should be defined prior to wider adoption.

## Mechanisms for Implementing Standardized Imaging

A number of bodies that represent imaging experts or users of imaging endpoints are optimally placed to develop consensus on imaging techniques and to disseminate recommendations. This includes government bodies such as the National Cancer Institute [101,177] and Cancer Research UK [130], accreditation bodies such as the American College of Radiology (ACR; http://www.acr.org) and the Intersocietal Accreditation Commission (IAC; http://www.intersocietal.org/intersocietal.htm), as well as the many professional societies related to medical imaging. ACR and IAC have traditionally provided voluntary accreditation for diagnostic imaging providers, although a recent U.S. health insurance quality improvement initiative and changes in Medicare law have mandated accreditation as a condition for insurance reimbursement. Standards have been established by IAC and ACR that specify the qualifications of imaging personnel, hardware quality control, conduct of imaging studies, image interpretation, and reporting. The scope of these standards is diagnostic imaging in clinical practice, and they are not directly applicable to imaging biomarkers. However, with the development of appropriate standards for quantitative imaging biomarkers, ACR and IAC may be ideally suited to facilitate the accreditation and education of imaging centers for imaging biomarkers.

In response to the need for quantitative imaging standards, the Radiological Society of North America (RSNA) has recently initiated the Quantitative Imaging Biomarkers Alliance (QIBA; http://www.rsna.org/Research/qiba_intro.cfm), represented by pharmaceutical companies, imaging hardware and software vendors, government agencies, imaging societies, RSNA leadership, and clinical trialists [178]. Modeled on the collaboration known as Integrating the Healthcare Enterprise (IHE; http://www.ihe.net/), QIBA aims "to advance quantitative imaging by focusing on standardizing the use of imaging biomarkers in clinical trials" with the long-term goal of "enhancing the use of quantitative imaging methods in clinical practice." Initially, planned efforts will address standardizing quantitative anatomical CT, FDG-PET, and DCE-MRI. Although QIBA has been formed under the auspices of RSNA, it seems probable that a dedicated standard setting organization may eventually be needed for ongoing development, maintenance, and dissemination of new imaging biomarker standards.

## MECHANISMS TO FACILITATE IMAGING BIOMARKER DEVELOPMENT

Despite the potential of imaging biomarkers as unique tools in drug development, the multidisciplinary nature and complexity of these technologies have somewhat hindered biomarker development. In addition, implementing and using imaging biomarkers has tended to be isolated to research institutions and centers with the necessary range of resources. The difficulties of imaging standardization and the expense of imaging biomarker qualification has also limited the incentive for commercialization of these technologies.

Many stakeholders in government and industry have recognized the inadequacy of traditional research and development approaches as applied to biomarker development. Other biomarkers in use today, such as blood pressure or plasma cholesterol, have taken decades to achieve their current utility [40]. In its Critical Path Initiative the FDA acknowledges the urgent need for new approaches and broad collaboration to address the unique challenges of biomarker development [179]. Two new approaches that are beginning to have a positive impact are public–private partnerships and the open-source development paradigm.

### Public–Private Partnerships

The Foundation for the National Institutes of Health (FNIH), in collaboration with the National Institutes of Health (NIH), the FDA, and the Pharmaceutical Research and Manufacturers of America (PhRMA), established in 2006 the Biomarkers Consortium [180], a public–private partnership focused on the discovery, development, and qualification of biomarkers, including imaging biomarkers, through collaborative biomedical research [181]. The Biomarkers Consortium is unprecedented in its size and coordination of government, academic, and industry aims for biomedical research focused on new biomarker technologies.

Government partners, including the NIH, FDA, and Centers for Medicare and Medicaid Services, contribute scientific and technical expertise as well as financial resources and project management to the consortium. Membership in the consortium is open to nonprofit and for-profit organizations and patient advocacy groups with an interest in helping the consortium reach its goals. Consortium members may nominate subject-area specialists as representatives on steering committees devoted to various therapeutic areas that are charged with evaluating biomarker project proposals. According to its Web site, "the Biomarkers Consortium wants all members to be actively engaged in this collaborative multi-sector approach to speed the discovery and validation of disease biomarkers and surrogates. Given the expense and logistical challenges of moving biomarker science forward, we've adopted this collaborative multi-sector approach that encompasses all relevant stakeholders."

Following biomarker project approval by the appropriate steering committee, private-sector fundraising for biomarker projects is facilitated by the FNIH.

Several large-scale imaging biomarker development and qualification studies have been initiated with assistance from the Biomarker Consortium. Two studies, to be conducted by the National Cancer Institute, are evaluating the utility of FDG-PET to monitor cytotoxic treatment of non-Hodgkin lymphoma and non-small cell lung carcinoma, providing data to support clinical qualification of FDG-PET as a possible surrogate endpoint [182]. A multicenter MRI study of carotid atherosclerotic plaque is determining the test–retest and intraobserver variability of MRI-based measures of plaque size and composition to facilitate imaging assay validation [183]. The Osteoarthritis Initiative (OAI) is a four-year, multicenter, longitudinal study of the clinical onset and progression of knee osteoarthritis which seeks to "characterize imaging, biochemical and genetic biomarkers that predict and track the course of [osteoarthritic] disease" [184]. Clinical data and images from almost 5000 patients will be made publicly available for further biomarker research worldwide [185]. The Alzheimer's Disease Neuroimaging Initiative (ADNI) is the largest project to date, with $25 million of its $60 million funding being raised through the FNIH. ADNI is a five-year study tracking 823 normal, mildly cognitively impaired, and Alzheimer disease patients using MRI and PET as well as laboratory and cognitive tests [186]. As with the OAI study, ADNI clinical data and images have been made available to the general scientific community for continued biomarker research and development [187].

These and other imaging-related projects supported by the Biomarker Consortium are addressing the need for clinical trials to establish the validity and clinical qualification of imaging biomarkers. Such trials would be too costly and would make little sense for any single organization to pursue but are made possible through collaborative sharing of the costs and associated risks among consortium members.

## Open-Source Collaboration

The success of the open-source paradigm for software development [188] has led to the open-source approach being applied to the development of biomedical informatics tools [e.g., Open Bioinformatics Foundation (http://www.open-bio.org) and Bioinformatics Organization (http://www.bioinformatics.org/)] as well as a gradual adoption of "open-source" collaborative models of biomedical research [189]. Key features of the open-source model are: (1) participation is open to anyone with the interest and skills to contribute; (2) development and communication is centralized through an Internet-based organization; and (3) the results are freely shared. Among drug development public–private partnerships, a hybrid approach is emerging in which the knowledge-based aspects of the research follow an open-source model, while "rule-based" aspects (such as toxicology, chemistry manufacturing and controls, clinical trials) are outsourced [190,191].

Large publicly funded research initiatives are similarly adopting an open-source approach. The cancer Biomedical Informatics Grid (caBIG; https://cabig.nci.nih.gov/) is an ambitious collaboration launched by the National Cancer Institute in 2003 to develop and share computing tools, infrastructure, and data across the spectrum of cancer research [192]. Data sharing follows a federated model [193] and integrates diverse cancer data from basic and clinical sources, as well as cancer imaging and tissue pathology data. A broad set of tools have been developed based on widely available open-source components and standards, including bioinformatics software, image analysis and database tools [194], and a complete clinical trials management system. Sharing of tools and data is facilitated by an open-source grid-based computing infrastructure. Although the focus of the caBIG research enterprise is cancer, the infrastructure and many of the tools are generic and may be useful in other therapeutic areas. One recent example has been the launch of the CardioVascular Research Grid (cvrGRID; http://cvrgrid.org) by the National Heart Lung and Blood Institute.

Given the complexity and difficulties of imaging biomarker development, it may be advantageous to apply the open-source paradigm to an integrated development effort for imaging biomarkers. As the foundational image-related tools from caBIG reach maturity, they could form the basis of an open-source development model that integrates image acquisition, analysis, protocol specification, cross-platform compatibility, data standards, validation, and qualification. Such an approach could address development and resource hurdles through the open participation of any interested party, standardization of protocols through centralized development and dissemination, and wide availability of common image analysis tools. Although some development issues would still need to be resolved, such as intellectual property protection and regulatory concerns, an open-source model may ultimately be the most efficient approach to developing, maintaining, and delivering the imaging biomarker tools that can affect drug development.

## CONCLUSIONS: CHALLENGES AND FUTURE OPPORTUNITIES

One of the most salient features of imaging science, which is relevant to both diagnostic imaging and imaging biomarkers, is that the state of the technology does not stand still. Continuous research and development for more than 30 years has produced a steady stream of new imaging technologies as well as incremental improvements that address the limitations of existing technologies. Development and implementation strategies for imaging biomarkers must account for this continuous change and attempt to balance the needs of standardization with the adoption of new innovative technologies. Like software, imaging biomarkers will probably need to be "versioned" to account for changes to the underlying technologies. However, this will also require a continuous process of development and maintenance, for which an open-source

model may be the most appropriate. Moreover, with the continued introduction of new imaging technologies, in the future we might expect the translation of additional image-based biological measures to promising new imaging biomarkers. This will become increasingly feasible as innovative systems make imaging biomarker development more routine.

It seems likely that no one biomarker will be able to adequately capture all of the important aspects of a given disease process or biological response to therapy. A combination of imaging and other biomarkers may be the most effective surrogate endpoint tool for drug development. In addition to the requirements of biomarker validation and qualification, this will require that the component biomarker technologies are cost-effective as a combination.

Current collaborative efforts being led by public–private partnerships such as the FNIH and by the NIH and QIBA are starting to address many of the hurdles of imaging biomarker development and standardization. New approaches that allow contributions from all stakeholders will accelerate the work of imaging biomarker validation and qualification, and we might expect that these initiatives will soon lead to broader availability of new imaging biomarker tools for drug development.

# PROTEIN BIOMARKER DISCOVERY USING MASS SPECTROMETRY–BASED PROTEOMICS

Joanna M. Hunter, Ph.D., and Daniel Chelsky, Ph.D.
*Caprion Proteomics, Inc., Montreal, Quebec, Canada*

## INTRODUCTION

Recent advances in biological sample preparation, automated sample handling, and sensitive mass spectrometry with a variety of sample ionization sources have catalyzed the emergence of these methods as tools for clinical proteomic analyses [1,2]. Concurrently, proteomic data analysis has been aided by the expansion and improvement of publicly available protein and gene databases. Among the methods reported for quantitative comparison of proteins of biological origin, several techniques based on liquid-phase separation of proteins and peptides rather than gel electrophoresis have been optimized and implemented within the last few years. These include stable isotope labeling as well as label-free methods [3–9]. Direct measurement and comparison of unlabeled peptide ion peak intensities has become the standard, particularly for high-throughput applications. Quantitative, label-free mass spectrometry–based methods for protein expression profiling include those based on pattern recognition [10,11], peptide counting [12–14], and peptide ion intensity or area [4,5,15–20]. Of these, the latter seems to be the most robust and applicable to clinical studies. The correlation between observed peptide intensity differences and protein abundance differences is the fundamental basis of label-free protein expression profiling. In particular, the rela-

tionship between liquid chromatography–mass spectrometry (LC-MS) signals and peptide abundance has been shown to vary linearly with concentration, even in complex samples [5,21–23].

Mass spectrometry–based protein expression profiling, without the use of labels or internal standards, is applicable to a wide range of sample types, including tissues, cells, organelles, and organisms, as well as body fluids such as plasma, cerebrospinal fluid, and urine. It has the additional advantage that comparisons can be made post hoc on a per patient basis, thereby dramatically increasing the granularity of information that can be obtained from the data. Multiple approaches can be taken for the label-free identification of differentially expressed proteins in large sample sets. At Caprion we have developed a specific approach, called Cell*Carta*, which has proven to be very effective and reliable. Features of this platform will be used as an example in describing issues and solutions for biomarker discovery.

The platform has low overall variability [<15% coefficient of variation (CV) in the absence of biological variability] and provides an accurate and quantitative measure of the biological modulation of protein abundance. Thus, statistically significant differences in plasma protein abundance can be detected, making this technology highly applicable to biomarker discovery in clinical samples. Plasma markers of disease, drug reversion of disease, predictive markers of drug response, pharmacodynamic markers of drug action, and early markers of both efficacy and toxicity can be detected using this technology. Studies may be conducted in animal models (preclinical) as well as with human clinical samples [24–26].

One requirement for a useful biomarker is that it can be measured in an easily accessible body fluid. In this regard, blood (serum or plasma) is preferred, and it is used routinely for many clinical assays [27]. However, the discovery of biomarkers in blood brings some technical challenges. Plasma has been estimated to contain anywhere from several hundred to several thousand proteins [28,29], whose concentrations are known to vary by up to 10 orders of magnitude. Many of the proteins with desirable biomarker characteristics are expected to be at the low end of the plasma protein dynamic range of concentration, typically at or below 100 ng/mL. Two approaches to this issue are described here. One approach depends on the immunoaffinity-based depletion of some of the most abundant plasma proteins, thus making it possible to see more of the lower-abundance proteins. The second approach is based on identifying and comparing plasma proteins just prior to release from their cells or tissue of origin. While residing in the secretory apparatus, proteins destined for the blood are highly concentrated, thus allowing for a comprehensive picture of tissue-specific markers.

## PROTEIN PROFILING PLATFORM FOR BIOMARKER DISCOVERY

One of the major challenges of biomarker discovery is the execution of unbiased large-scale studies to avoid the confusion of process artifacts with actual

biomarkers. Unbiased experimental design and study implementation are arguably among the most critical components of a differential protein expression platform [30]. Because subtle errors in a work plan can result in large biases, careful study planning and implementation are necessary in order to discover biomarkers that are robust to population variation, sample collection variability, processing artifacts, and other confounding factors. The first step in setting up a study is to clearly define the questions that must be addressed. From these goals, the minimum number of patients in each condition to be compared can be fixed. Although the group sizes can be small from a purely analytical perspective, the number of samples required is dictated by the possibility of confounding factors within the target group and/or by the need to sample a diverse target population. Multiple comparisons across large sample sets are achievable and fully exploit the analytical platform. In addition, the order in which samples are processed and analyzed must be considered. Depending on the comparisons to be made, samples must be interleaved and/or randomized between processing steps. Alternatively, the samples to be compared are block randomized, with comparisons made within each block, thus ensuring the greatest processing consistency within a comparison. After samples have been processed, data analysis techniques are employed to ensure that biases have not occurred. If biases appear, appropriate sample pairing and statistical tests are utilized to ensure that the biases do not influence the conclusions drawn from the study.

To generate highly reproducible results, stringent control of sample preparation, analysis, and data normalization procedures are required. Low peptide signal intensity variation across study samples is required to detect statistically significant and subtle protein changes against background variation. Protocols followed rigorously, including quality control checks, are necessary throughout the study, from sample collection to data analysis. For example, strictly following a standard operating procedure (SOP) for blood collection and generation of plasma enables blood samples to be collected from multiple sites for the same study. Furthermore, a well-documented sample "chain of custody" is obligatory when handling clinical samples. As part of this documentation process, samples are barcoded, logged into a laboratory information management system (LIMS), and stored in locked freezers. All subsequent steps in sample handling and analysis are monitored and logged, and all data are secured. Thus, SOPs and quality control procedures ensure sample integrity throughout the process. Specific features of the Cell*Carta* work flow are detailed below.

## Focusing on the Relevant Proteome

Without enrichment of a targeted proteome, samples contain far too many proteins to be visualized in a reasonable number of analytical runs, and only the most abundant proteins are detected. Enrichment of subproteomes is necessary to reduce the sample complexity and to decrease the limit of detection. More comprehensive protein identification as well as information on

subcellular localization is obtained by isolating organelles such as plasma membranes, endosomes, phagosomes, mitochondria, endoplasmic reticulum, nuclei, or Golgi apparatus from cells or tissue homogenates. Similarly, blood (plasma or serum) is enriched for lower abundance proteins by the removal of high-abundance proteins. For example, depletion of the 14 most abundant proteins using the Multiple Affinity Removal System (MARS, Agilent Technologies) removes over 96% of total protein and consequently enhances the detection of the remaining lower-abundance components [31,32]. Various depletion approaches are being used to get deeper into the plasma proteome [33]. The key criteria for implementing enrichment or depletion strategies are that they provide minimal contamination of the nontargeted proteins and are highly reproducible.

## Sample Fractionation

Regardless of the origin of the purified protein samples, the complexity is typically too great—both in terms of the number of proteins and the dynamic range of concentration—for direct analysis by mass spectrometry. Reversed-phase liquid chromatography coupled to mass spectrometry (LC-MS) can reproducibly distinguish and quantify over 5000 peptides in an hour-long analytical run. A single LC-MS injection is therefore suitable for samples comprised of some 500 to 1000 proteins. Subproteome enrichment typically reduces the total number of proteins to fewer than 10,000. To characterize these complex samples more comprehensively, a fractionation step must be applied before the LC-MS. At the protein level, separations such as strong anion exchange provide effective fractionation prior to trypsin digestion and LC-MS. Alternatively, the proteins are first proteolyzed to tryptic peptides, with subsequent separation of the peptides by strong cation exchange (SCX) liquid chromatography [34]. The Cell*Carta* work flow employs this method.

## Differential Protein Expression by LC-MS

For optimal matching of peptide signals across many samples, the LC-MS platform must be as reproducible as possible (Figure 1). Technically, the requirements of stable chromatography, high resolution, and mass accuracy may be addressed by a variety of instruments. Peptide profiling takes place on mass spectrometers that are capable of providing sensitive, high-mass-accuracy measurements, such as time-of-flight or high-resolution ion-trapping instruments. Peptide sequencing is performed on quadrupole-time-of-flight instruments such as the QSTAR (Applied Biosystems) or the QTOF (Waters), or on an ion trap such as the LTQ-Orbitrap (ThermoFisher), which are sensitive and can provide high-quality MS/MS spectra. Regardless of the mass spectrometer type, capillary reversed-phase LC columns are coupled to these instruments via an electrospray interface. The Cell*Carta* mass spectrometry platform utilizes capillary liquid chromatography (CapLC) and QTOF LC-MS

**Figure 1** Consistent peptide intensity across all samples allows the detection of differentially expressed peptide ions. Shown is a partial view of peptide ion maps (as measured by LC-MS) from the plasma of three individuals. The horizontal axis is chromatographic retention time, the vertical axis is mass-to-charge ratio ($m/z$), and the peptide ion intensity is denoted by the size and color of the spots. The peptide ion circled shows differential expression across patients and increases in abundance from sample 1 to sample 3. (*See insert for color reproduction of the figure.*)

systems (Waters). The LC-MS measurements are reliable and reproducible, providing a median CV of peak intensity of 8 to 9% for peptides matched across six replicate injections of a standard sample.

To quantify the differentially expressed peptides, a suite of proprietary bioinformatics tools was developed at Caprion and implemented into Cell*Carta*. Matching peptides across large sample sets (peak alignment) is the first step in the differential expression analysis (Figure 2). Algorithms to perform mass-to-charge ratio ($m/z$) and chromatographic retention-time alignment result in the confident detection of significant peptide intensity differences between samples. Peptide ions are detected and matched across all the samples in the study. Each study peptide is characterized by $m/z$, charge, retention time, and intensity. Bioinformatics software tools map peptides across all samples, comparing ion intensity for all reproducible peptide ions across all fractions. Those peptides that show a statistically significant differential abundance are targeted for protein identification.

## Protein Identification

Identification of the candidate protein biomarkers is accomplished using two different and complementary tools. First, database searching of LC-MS/MS spectra for peptide identification is accomplished using Mascot (MatrixScience), which searches for the best fit between the recorded spectra and theoretical spectra calculated from tryptic peptides from proteins in the reference

**Figure 2** Related peptide ions are clustered across the entire study. High confidence matching is achieved, independent of small variations in mass and retention time detected. Each symbol represents a detected ion in one sample, plotted at the observed mass-to-charge ratio and chromatographic retention time.

database. For human plasma studies, the human International Protein Index (IPI; European Bioinformatics Institute) is searched. For samples not of human origin, other public databases may be used, depending on the species. The search results are parsed based on peptide and protein score thresholds that are determined by setting an acceptable false-positive rate of identification calculated by searching a randomized database [35].

In addition, we have developed novel software that adds a differential abundance correlation filter to mass and retention-time fingerprinting [virtual mass spectrometry (VMS)]. Protein identification using mass and retention-time fingerprinting alone suffers from the high level of mass redundancy for peptides from complex species. VMS incorporates the protein identification and peptide expression resolver (PIPER) filter, which requires all peptides pointing to the same protein to share the same relative intensity across all samples, a logical requirement for association. Application of the PIPER filter to the identified peptides results in false-positive protein identification rates below 5% [36]. This method provides for the identification of proteins where the peptide ions can be detected but are not sufficiently intense to provide an interpretable MS/MS fragmentation pattern [37]. In addition to adding new protein identifications, VMS can also be used to supplement LC-MS/MS by

increasing confidence in low-scoring sequence matches or single-peptide identifications. Thus, the combined use of LC-MS/MS sequencing with VMS greatly expands the ability to identify and quantify novel proteins by expanding the dynamic range (number and concentration) of identifiable proteins as well as the confidence (number of identified peptides per protein) of protein identification.

## Candidate Biomarker Results Visualization

Proteomics analyses can often generate large data sets, including all of the associated peptide sequence and expression data. To enable rapid evaluation and interpretation of results, it is very helpful to organize the output into a searchable database with a specialized but simple user interface. We have created such a tool that is Java-based and accessible on a secure Web portal. The Data Report provides query, filtering, and data analysis capabilities as well as visualization of peptide differential expression and protein identification across all of the samples in the study. Included in the Data Report are listings of all the peptides, protein accession numbers, and gene names identified, along with differential expression information for each. Graphical displays of peptide intensities, differential expression, and MS/MS spectra are also available (Figure 3). In addition, selected data can be exported into standard formats.

## Candidate Biomarker Panels

Historically, circulating biomarkers have been defined by a single analyte that can be used to distinguish given groups of individuals with high specificity and sensitivity (positive and negative predictive values). In the last two decades, the development of high-throughput multivariate analytical platforms, such as protein and gene chips, has enabled the identification and validation of multivariate biomarkers. Due to population variation and the multitude of effects that treatment can have within a person and across the population, it is acknowledged that panels of proteins are likely to produce a biomarker that is significantly more sensitive and specific than any single protein alone [38].

In a typical biomarker discovery study performed on the Cell*Carta* platform, hundreds of proteins are found to be significantly differentially modulated. These proteins are then prioritized into panels of 3 to 10 proteins. This process involves filtering based on several criteria, including diagnostic strength [i.e., the area under the receiver operator characteristic (ROC) curve or AUC] and linear regression to clinical factors. In particular, the panel of proteins must have a high composite AUC in addition to strong individual protein AUC scores. Biomarker panels with high discriminating power (positive and negative predictive values) can thus be composed from the individual biomarker candidates. The number of protein candidates included in the panel

**Figure 3** Caprion Data Report user interface. An example Data Report screenshot is shown. The upper left panel contains a summary of the proteomic data for the proteins selected by the user. The upper right panel contains several tabs that permit additional details to be displayed, including a hierarchical clustering of the peptides. The lower left panel contains search options, while the lower right panel contains several tabs that provide additional proteomic data, such as peptide intensities, differential expression, and MS/MS spectra.

represents a trade-off between cost and risk. Although larger protein panels are more costly to verify, they are more resilient to population variability. Prioritized candidate biomarkers are then qualified and verified further using immunoassays such as enzyme-linked immunosorbent assay (ELISA) or mass spectrometry–based assays such as multiple reaction monitoring (MRM) [39,40].

## PROTEIN BIOMARKER DISCOVERY IN BLOOD PLASMA

The Cell*Carta* platform enables the measurement of biological changes of interest in human plasma profiling studies for protein biomarker discovery. The following examples illustrate that protein biomarkers can be found in plasma using a highly controlled proteomics technology platform and employing an appropriate study design.

## Global Proteomics Applied to Alzheimer Disease

A collaboration with Hyman Schipper, a neuropsychologist at the McGill University Memory Clinic, part of the Jewish General Hospital (JGH; Montreal, Canada), was undertaken to investigate the effect of drug treatment on Alzheimer disease (AD) patients. Plasma was collected from patients after obtaining written informed consent and with approval of the research and ethics committee of the JGH. Included in the study were 33 age-matched healthy control, 19 untreated AD, and 25 donepezil-treated AD patients. Each patient was administered the Folstein Mini-Mental State Examination (MMSE), a qualitative test of disease severity [41]. In addition, clinical histories were obtained.

In the course of the study, a "global proteomics" approach to data visualization and analysis was developed and implemented. Following unsupervised clustering by multidimensional scaling (MDS), the untreated disease group was found to cluster apart from the healthy group (Figure 4). Subsequently, a centroid (median value in three dimensions) was calculated for each group. The line intersecting the normal and disease group centroids is defined as the

**Figure 4** Global proteomics analysis on Alzheimer disease and normal patients. Multidimensional scaling of proteomics data demonstrates the separation of healthy individuals (green spheres) from Alzheimer patients (red spheres). Caprion has defined a disease axis that is used to quantify relative disease state. The axis is a line that passes through the disease and healthy centroids (yellow spheres). Each patient is then positioned on the axis according to its orthogonal intercept. Donepezil-treated Alzheimer patients (purple spheres), as a group, are shifted on the disease axis from the disease group toward the healthy group. (*See insert for color reproduction of the figure.*)

*disease axis* (Figure 4). The disease severity for each patient is indicated by the distance between its orthogonal intercept with the disease axis and the normal centroid. The disease severity of each patient, as determined by this approach, correlated well with the patient MMSE score, with a Pearson correlation coefficient of 0.75. When the relative position on the disease axis was matched to relative peptide intensity, 282 peptides were found to correlate with the disease severity profile. The proteins corresponding to these peptides were subsequently identified. Although there is currently no blood-based diagnostic test for AD, these results suggest that a test monitoring blood protein levels could measure AD severity.

The global proteomics approach was applied to assess the effect on AD patients of treatment with donepezil. A total of 75 peptides were found to be highly correlated with the disease severity profile of treated versus untreated AD patients. These peptides are a subset of the 282 disease-related peptides. The Cell*Carta* platform can thus be employed as an assay that enables the analysis of drug response for patient segregation. As an extension, pharmacodynamic analyses such as dose optimization and drug efficacy could be performed using this method. This study demonstrates that global proteomics can be an effective approach to pharmacodynamic biomarker identification.

## Oncology Biomarkers: Blinded Case Study

The goal of this second study was to identify circulating markers of ovarian and breast cancer. Two sets of patient samples were examined. The first set was composed of eight samples each from patients with breast cancer or ovarian cancer as well as eight matched healthy subjects. The second set of samples had the same composition, but the identities were blinded to Caprion. All samples were processed concomitantly though the Cell*Carta* platform. Of the 53,628 peptide ions detected across the study, 4089 were differentially modulated reproducibly and significantly ($p < 0.005$) in one of the three cohorts. These peptides were further analyzed by the bioinformatics tool, multidimensional scaling, to determine the relationship between each of the patients at the global proteomics level. Results, shown in Figure 5, indicate that each of the three groups of samples cluster separately. The samples in each group are therefore more similar to other members of the same group than to members of other groups. This similarity within a group translates to peptides (and proteins) that distinguish and separate each group.

The behavior of the peptides that were found to distinguish each of the three groups was analyzed for each of the 24 blinded samples. Each sample was therefore categorized according to which of the three groups it was most related. When the samples were unblinded, it was determined that 22 of the 24 assignments were correct. Only one pair, consisting of a normal and a breast cancer plasma sample, was assigned incorrectly.

In this example, all differentially expressed peptides were used to discriminate the three groups in order to maximize the ability of the small learning

**Figure 5** Sample groups distinguished by differentially expressed peptides. Multidimensional scaling analysis was performed using the intensity values for 4089 differentially expressed peptide ions from 24 samples. Separation along three axes of variance (MDS1 to MDS3) is shown, where each sphere represents a patient sample. The groups are identified by the colors indicated. (*See insert for color reproduction of the figure.*)

set (first 24 samples) to determine the identity of the blinded sample test set. None of the individual peptide ions could discriminate the three groups very well. However, sets of five or 10 peptides were much more effective, as shown in the receiver operating characteristic (ROC) plots in Figure 6. In the case of multiple peptide analysis, peptides were chosen randomly from the population of differentially expressed peptides in order to provide multiple examples of the range of discrimination possible. The AUC required to fully discriminate groups is a value of 1. This was most frequently achieved as the panel size increased from one to 10 proteins (Figure 6, right panels).

To better understand the biology underlying the differentially expressed peptides, their parent proteins were identified. This was accomplished by LC-MS/MS and VMS to identify groups of peptides representing a single protein. This result was further filtered by requiring that the relative intensity of a minimum of three peptide ions be well correlated across all samples. Approximately 200 proteins met these and other strict confidence criteria. Half of these proteins distinguished either breast cancer or ovarian cancer from the other two conditions. The remaining half of the proteins distinguished cancer (breast or ovarian) from normal healthy subjects. These results suggest that circulating blood proteins provide a rich source of high-quality

**Figure 6** Multiple peptide panels are effective at discriminating groups. ROC plots show improved performance when going from one to five to 10 peptides. Displayed are curves (left) representing true-positive ($x$-axis) and false-positive ($y$-axis) ratios and the area under the curve (AUC; right column) for single-peptide (top), five-peptide (middle) and 10-peptide panels (bottom). In the case of multiple-peptide analysis, peptides were chosen randomly from the population of differentially expressed peptides. The optimal AUC for discriminating groups is a value of 1. This was best achieved as the panel size increased. (*See insert for color reproduction of the figure.*)

disease biomarkers that can be discovered using mass spectrometry–based protein expression profiling.

## PROTEIN BIOMARKER DISCOVERY IN THE SECRETORY APPARATUS

### Secreted Proteins as Biomarkers

In the quest for circulating biomarkers of disease or drug response, much effort has been made to avoid the overwhelming effect of high-abundance proteins in the blood that obscure lower abundance and potentially more interesting proteins. Removal of the high-abundance proteins with multiple affinity antibody columns has been very effective in this regard. An alternative approach that has been successful as well is to isolate plasma proteins as they are being released from the source tissues or cells. One common such method involves harvesting proteins released by tissue culture cells into conditioned media [42,43]. Although this approach has been productive, proteins may be lost due to dilution or adherence to the culture container, and it is generally limited to cultured cells rather than whole tissue. Analysis of tissues can provide a more physiological context, as they include primary cells as well as the natural composition of multiple cell types that may modulate secretion. Tissues can also be taken from the host, typically animal models of disease, following drug treatment, in order to assess the impact of treatment on the secretome. This can lead to a better understanding of the mechanism of action of the drug treatment as well as the identification of possible markers of therapeutic response. Proteins released from tissue into culture medium have also been studied [44], but contamination from lysed cells and culture medium can obscure the actual proteins secreted. Reliance on those proteins with a signal sequence as well as isotopic labeling of de novo synthesized proteins from the tissue are usually necessary.

An alternative approach to identifying and quantifying secreted proteins relies on the isolation of such proteins directly from the secretory pathway of the cells or tissue. The contents of the Golgi and related secretory vesicles provide a highly concentrated collection of proteins, just prior to their release from the cell [45,46]. This method avoids dilution into the plasma, which would obscure all but the more abundant secreted proteins. Dilution as well as contamination by cell lysis proteins in culture medium is also eliminated as a concern. Tissues can be as easily investigated as cultured cells, with the added advantage that the samples do not need to be viable at the time of analysis. Thus, frozen surgical samples from patients or animal models are amenable to study and comparison, even when samples are collected at different time points. To isolate secretory proteins directly from cell culture or tissue, the homogenized samples are separated on a density gradient to isolate secretory vesicles.

## Secreted Proteins Differentially Expressed in Prostate Cancer

The prostate secretes a range of proteins related to its function, including proteolytic enzymes, acid phosphatase (ACPP), and prostate-specific antigen (PSA). In prostate tumors, some of these proteins are known to increase or decrease in the amount secreted. To test the application of secretory vesicle isolation to frozen human surgical specimens, samples were obtained from patients with prostate cancer, with institutional review body (IRB) approval and patient consent. Tumor and normal tissue were separated as described [47] and the content of the secretory apparatus was isolated. Proteins were digested with trypsin and analyzed by LC-MS in order to compare expression between each normal and tumor pair from all six patients. Significantly differentially expressed peptides were identified. Four of the best known prostate cancer–associated secreted proteins were found to be up-regulated, as expected, in the tumors. PSA, ACPP, kallekrin 2 (KLK2), and macrophage migration inhibitory factor (MIF) are all low-abundance proteins in the blood, at levels ranging from 0.2 to 3.5 ng/mL in normal individuals. Detection of these proteins by direct LC-MS analysis of plasma would not be possible, yet was readily accomplished by examination of the secretory pathway. Two of these proteins, PSA and MIF, were also evaluated by commercial ELISA in the plasma of the same patients. The levels observed in the secretory vesicles by unlabeled mass spectrometry were directly comparable to levels in the plasma from the same patients, with correlation coefficients of 0.69 and 0.74, respectively [46]. Thus, analysis of differentially expressed proteins in the secretory apparatus is predictive of relative expression in the plasma. This correlation means that discovery can be done in the highly concentrated milieu of the vesicles, while verification and validation studies can be conducted with more sensitive antibody-based assays directly in blood.

In addition to the well-known prostate cancer markers, other known cancer-related proteins were found, for a total of 40 proteins with known cancer association. A further 20 proteins were identified as differentially expressed in the tumors that were not previously known to have a cancer association. The known function of the proteins typically fit well with their observed expression patterns. For example, of 11 proteins involved with sugar metabolism, all were found to go up in the tumors. On the other hand, of nine proteins involved with contraction and adhesion, six were found to be expressed at lower levels in the tumor samples than in the matching normal tissue.

## Proteins Secreted by Visceral Adipose Tissue

Visceral adipose tissue is much more than a storage medium for excess energy. This realization came with the discovery in 1994 of leptin and its wide-ranging activities, which include reduction of appetite, angiogenesis, hematopoiesis, and bone formation [48–50]. Visceral adipose tissue is now recognized as an endocrine organ that releases a large number of biologically active molecules

called adipokines, which have pleiotropic effects on a variety of metabolic pathways [48,51]. Proteins released from adipose tissue include regulators of inflammation, inducers of angiogenesis, and modulators of hypertension, among others. Visceral adipose tissue, in particular, has been implicated in the release of proteins responsible for metabolic syndrome and type 2 diabetes [52]. For this reason, evaluation of visceral adipose tissue, either alone or in comparison to subcutaneous adipose tissue, is of great interest [52,53].

As a pilot study of the eventual comparison of proteins secreted from visceral and subcutaneous adipose tissue, visceral adipose tissue was obtained from three obese patients undergoing gastric bypass surgery. The contents of the secretory apparatus were isolated from each subject and analyzed by LC-MS/MS to determine feasibility and yield, as well as to catalog the proteins and verify that known adipocyte-secreted proteins could be found. In a limited analysis, 155 proteins were identified, including many of the well-known adipokines. Among the proteins identified were cytokines (TGFb1; IL 25), acute-phase proteins (SPARC; lipocalin 2/NGAL), proteins that regulate blood pressure (angiotensinogen; ARTS-1), regulators of lipid metabolism (retinol-binding protein 4; lipoprotein lipase), and signaling molecules (galectin-1; prohibitin). Only 65 of the proteins were also found in one of three secreted-protein databases [54–56]. Although this could suggest that some of the proteins are contaminants, it could also point to the possibility that many secreted proteins are missed by conventional discovery methods that typically screen for proteins with an N-terminal signal sequence [44,57]. Some well-known

**TABLE 1 Five Proteins Found in the Secretory Apparatus of Human Visceral Adipose Tissue That Are Targets for Therapies in Clinical Trials**

| Target | Condition | Drug | MoA | Phase |
|---|---|---|---|---|
| Leucocyte elastase | Acute respiratory distress syndrome | Depelestat | Inhibitor of elastase activity | II |
| Transforming growth factor-b-1 | Pulmonary fibrosis | GC1008 | Neutralizing antibody | I |
| Clusterin | Lung and prostate cancers | OGX-011 | Inhibition of gene expression | II |
| Transthyretin (TTR) | Familial amyloidosis | Diflunisal | Stabilization of TTR to prevent formation of amyloid fibrils | III |
| Pigment epithelium-derived protein | Macular degeneration | AdGVPEDF.11D | Gene therapy | I |

secreted proteins, including FGF-1, FGF-2, IL-1, and galectins, do not have a classical N-terminal signal sequence [58]. Direct detection of these nonclassical secreted proteins will be an important approach to expanding on the secretome as well as validating the predictive tools currently under development for these proteins, such as SecretomeP [59].

An important aspect of studying the contents of the secretory apparatus is the ability to identify low-abundance secreted proteins that would be difficult to detect without specific antibodies, such as IL-25, TGFb1, and lipocalin 2. Also important is that the proteins identified have important biological functions that could eventually aid in the discovery of novel approaches to therapeutics. Of interest, therefore, is the observation that five of the proteins identified in the pilot adipose tissue study are current targets of therapies in clinical trials (Table 1). These therapies are not necessarily involved in adipose-related diseases, but still serve to demonstrate that proteins identified by this approach include those that are important to drug discovery.

## SUMMARY

The global proteomics approach for candidate biomarker discovery using label-free mass spectrometry-based methods is able to detect significantly differentially expressed proteins in a variety of biological systems. An advantage of this technology is that it enables varied study designs involving comparisons between large cohorts or multiple experimental conditions. For example, pharmacodynamic markers of drug treatment, markers of disease severity, or predictive markers of efficacy may be discovered, depending on the study design. Candidate biomarkers are combined into panels having sufficient discriminating power (positive and negative predictive values) to provide meaningful diagnostic or prognostic information and perform better than single-protein biomarkers against broad populations. Consequently, these high-confidence panels provide biomarkers that appear suitable for development into high-throughput screening assays.

Multiple approaches to identifying lower-abundance proteins in plasma have demonstrated value, including antibody depletion of high-abundance proteins as well as the analysis of the contents of the secretory apparatus. These two techniques are seen as complementary in terms of the plasma protein concentration range interrogated. Typically, the limit of detection of direct analysis of plasma or serum proteins is approximately 10 to 100 ng/mL, which has proven to be a very productive range for candidate biomarker identification. The blood concentrations of proteins secreted from Golgi lumen are approximately two orders of magnitude below this, allowing for an even more comprehensive view of the low-abundance tissue-specific blood proteome. Further improvements are expected in the future, but clearly the tools now exist to identify novel and useful biomarkers of disease and drug response.

# QUANTITATIVE MULTIPLEXED PATTERNING OF IMMUNE-RELATED BIOMARKERS

Dominic Eisinger, Ph.D., Ralph McDade, Ph.D., and Thomas Joos, Ph.D.
*Rules Based Medicine, Inc., Austin, Texas*

## INTRODUCTION

The human immune system is a complex cellular and molecular network unlike any other biological system. The complex interplay of multiple immune cells that rid the body of foreign invaders and diseased tissues is governed by a vast number of cell-to-cell communications. In this chapter we focus on the expanding utility of measuring these secreted protein messengers as biomarkers for drug development and diagnostic efforts that are relevant to a variety of diseases. Herein we use a broad acronym, IB (immune-related biomarker), to represent protein biomarkers for a variety of immune-related disorders. The IBs most prominently monitored in drug development efforts are the cytokines and chemokines, but also include acute-phase reactants, tissue remodeling factors, vascular markers, and growth factors. This complexity has led to the rapid adoption of newer multiplexed measurement tools. Key features of these include the quantitation, sensitivity, and perhaps most important, precision of each measurement. Ecosanoids, prostaglandins, prostacyclins, the thromboxanes, and the leukotrienes are also key elements of immune processes but do not fit under the paradigm of protein biomarkers and are not addressed in this chapter.

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

This ability to measure multiple IBs simultaneously from a small biological sample has ushered in an era of exploration known as *biomarker patterning*. It would be convenient if the single biomarker paradigm of the past were to continue unabated. However, the rate of introduction of new U.S. Food and Drug Administration (FDA)–approved diagnostic protein assays has fallen dramatically to an average of one or less per year [1]. This unfortunate trend does not suggest relying on a single biomarker but, rather, a group or set of biomarkers for drug development and diagnostic efforts. The theory of biomarker stacking is that by combining the predictive power of each marker, the optimal sensitivity and specificity of the multiplexed test will be achieved [2]. Rather than a single biomarker to fit with a specific disease or drug effect, a pattern of multiple biomarkers provides stronger predictive value, due to their "stacking" effects. In this chapter we focus on the multiplexed immunoassay measurement technologies as well as some recent and relevant examples of successful biomarker patterning. These approaches are rapidly bringing multiplexed biomarker assays into everyday use in drug development and diagnostics for personalized medicine.

## MEASUREMENT PROTEOMICS VS. TRADITIONAL PROTEOMICS

Multiplexed immunoassays used to identify novel biomarker patterns is a form of proteomics. However, it is often confused with traditional proteomics, which typically use complex separation technologies such as two-dimensional gel electrophoresis and/or mass spectrometry to identify patterns of peaks that are peptides or proteins of unknown origin. This approach provides new targets for future research but lacks the quantitation and certainly the precision necessary for clinical use. In contrast, the approach discussed here measures only those analytes where a specific assay has been developed. It requires specific ligand-binding reagents, generally antibodies, and a physical address to localize that binding reaction. This technique has been described as *measurement proteomics*, where a restricted set of analytes is measured and data reported in absolute terms (e.g., pg/mL) [3].

One caveat of measurement proteomics that must be addressed is the inherent variability among individuals for expression of different IBs. This variation results from a blend of genetic and environmental factors. Before one can accurately predict the biological response to a disease or its therapy, the natural variance within a population as well as within a person must be determined for the protein analytes in question. This is typically performed by assessing the biomarker patterning data for a control group of people while simultaneously measuring the identical markers in the diseased or drug-treated group. Statistical tools and means are widely available to use either cutoff values for individual analytes or multivariate analysis for multiple biomarkers in order to achieve a valuable test. Experience has shown that the level of a given protein biomarker or biomarker pattern often correlates with a particu-

lar disease state. In addition, these biomarker levels in serum or plasma have been shown to be stable in a person over time [1,2].

## MEASUREMENT PROTEOMICS PLATFORM TECHNOLOGIES

### ELISA-Based Immunometric (Sandwich) Immunoassays

Many of the key IBs (cytokines and chemokines in particular) exist at relatively low concentrations in serum or plasma, requiring the femtomolar sensitivity provided by the sandwich immunoassay. Sandwich immunoassays get their name from the fact that the antigen is "sandwiched" in between two antibodies. This is typically a more sensitive technique than single-antibody competitive assays. Traditional single-plex methods such as the 96-well microtiter plate–based enzyme-linked immunoassay (ELISA) use a capture antibody anchored either hydrophobically or covalently to the polystyrene wall of each well. After binding of antigen from the liquid sample, the assay is completed by adding a second antibody solution specific for the same target, thus completing the sandwich. A reporter signal attached to the second antibody provides the quantitative signal. ELISAs have been the standard in the research lab for decades, while the same sandwich immunoassay technique has been applied in a more industrial fashion in fully automated random access immunoanalyzers such as the Immulite from Siemens, built for FDA-approved assays in the clinical lab.

### Multiplexed Immunometric (Sandwich) Immunoassays

The random access immunoanalyzers found in the clinical lab do provide a form of multiplexing by physically splitting the loaded serum or plasma sample into multiple single-plex assays. Although this is an efficient approach for the work flow in a lab, it still requires a minimum of sample volume for each assay and does not reduce the cost per assay significantly. True multiplexing, as delivered by today's newer platforms, does provide significant savings in both the sample volume requirements and the cost per assay. Although a number of interesting multiplexed immunoassay platforms have been launched in the last decade, two primary types of platforms have survived as viable commercial entities: planar arrays and microsphere-based arrays.

### Planar Arrays

Planar microarrays are highly miniaturized and parallelized solid-phase assay systems that use a large number of different capture molecules immobilized in physically addressable locations called *microspots*. These spots, which typically have diameters of less than 250 μm and are arrayed in rows and columns,

are where the capture antibody for each assay is deposited. This deposition by physical touching with pins or spraying with piezoelectric tips is a technologically demanding step that was first pioneered in the gene expression industry for detection of nucleic acids by sequence-specific hybridization [4]. This approach has been used to generate antibody arrays consisting of several hundred capture antibodies by depositing them on nitrocellulose-coated microscope slides. Typically, these large arrays have then been probed either by using a direct labeling approach, where the mixture of antigens is fluorescently labeled; or conversely, a cocktail of second antibodies labeled with a fluorescent tag have been used to complete the sandwich assays. In either case, quantitation was achieved by imaging the spots with a change-coupled device (CCD) camera. The two limiting features of this approach have been (1) the irreproducibility of the spotting approach, where each new array is considered a new lot of material from a quality control point of view; and (2) the high probability of antibody–antibody interactions when greater than 25 antigen–antibody reactions are performed in a shared physical space. The second is a limiting factor for all multiplexed immunoassays and has been considered in the three most popular platforms.

### Microtiter-Based Planar Arrays

Glass slide–based immunoassay microarrays have been adapted to the microtiter plate format to increase throughput and to use existing automated solutions. Although this limits the number of microspots available per well, it helps to avoid the problem of antibody–antibody interactions. Such an approach was adapted by Thermo Scientific with their SearchLight Protein Array Technology. On the bottom of each microtiter well, an array consisting of up to 16 microspot features are generated, which allows the measurement of 16 analytes from 50 μL of sample. After incubation with sample, the wells are washed as with an ELISA and the captured antigen visualized using a secondary antibody labeled with a chemiluminescent probe. Quantitation of captured analytes is provided by a CCD imaging system using a calibration curve set up in parallel wells (www.piercenet.com).

Meso Scale Discovery (http://www.meso-scale.com) also uses a microtiter well microarray strategy called Multi-Array. Each well is arranged with 1 to 25 carbon microspots that are in essence miniature electrodes integrated into the bottom of the plate. Onto each carbon electrode the capture antibodies are immobilized, which after multiplexed immunoassay development results in a bound electrochemiluminescent (ECL) label. Quantitation of each assay is performed by passing electrical current through each electrode, producing a luminescent signal which is detected by a CCD camera imaging system. The microtiter plate format allows the use of standard liquid-handling automation with a multiplexed control and calibration strategy. As each Multi-Array plate can be imaged across all 96 wells within a few seconds, the sample throughput of this approach is large and quite scalable. The ECL detection system is also

thought to provide significantly better sensitivity for immunoassays than can be provided by chemiluminescence or fluorescence.

The two planar array systems described above are typically operated in a manual mode, although both are capable of interfacing with automated liquid-handling systems. One fully automated planar array system in the marketplace is the Evidence, an automated biochip system developed by Randox Laboratories (http://www.randox.com). It provides multiplexed analysis of miniaturized and parallelized immunoassays in a macroarray format. This macroarray contains 25 features and uses a chemiluminescence-based readout. Several immunoassays panels are available, including fertility, cardiac disease, tumors, cytokines and growth factors, and drug residue panels.

## Microsphere Arrays

Robust and flexible microsphere-based array systems have been developed over the last decade [5]. For the purposes of this review, there is only one microsphere-based array developed and commercialized in a manner parallel to the planar array discussed previously that has succeeded in garnering the most significant portion of the multiplexed immunoassay market: xMAP from Luminex Corporation (http://www.luminexcorp.com). Luminex technology can perform up to 100 multiplexed, microsphere-based assays in a single reaction vessel by combining optical classification schemes, biochemical assays, flow cytometry, and advanced digital signal-processing hardware and software.

Multiplexing is accomplished by assigning each analyte-specific assay a microsphere set labeled with a unique fluorescence signature. To attain 100 distinct microsphere signatures, two fluorescent dyes, red and infrared, are mixed in various combinations using 10 intensity levels of each dye (i.e., $10 \times 10$). Each batch or set of microspheres is encoded with a fluorescent signature by impregnating the microspheres with one of these dye combinations. After the encoding process, assay-specific capture antibodies are conjugated covalently to each unique set of microspheres. Coupling is performed on large numbers of individual microspheres ($10^7$ to $10^9$ microspheres) simultaneously within each unique set, resulting in low microsphere-to-microsphere variability.

After optimizing the parameters of each assay separately, multianalyte profiles (MAP) are performed by mixing up to 100 different sets of the microspheres in a single well of a 96-well microtiter plate. A few microliters of sample is added to the well and allowed to react with the microspheres. The assay-specific capture reagent on each microsphere binds the analyte of interest. A cocktail of assay-specific, biotinylated antibodies is reacted with the microsphere mixture, followed by a streptavidin-labeled fluorescent "reporter" molecule (typically, phycoerythrin). Finally, the multiplex is washed to remove unbound detecting reagents.

After washing, the mixture of microspheres is analyzed using a Luminex instrument which uses hydrodynamic focusing to pass the microspheres in

single file through two lasers. As each individual microsphere passes through the excitation beams, it is analyzed for size, encoded fluorescence signature, and the amount of fluorescence generated in proportion to the analyte. Microsphere size, determined by measuring the 90° light scatter as the microspheres pass through a red diode laser (633 nm), is used to eliminate microsphere aggregates from the analysis. While in the red excitation beam, the encoded red and far-red dyes are excited and the resulting fluorescence signature (ratio 660 nm/720 nm) is filtered, measured using avalanche photodiodes, and classified to a microsphere set. Since each microsphere is encoded with a unique signature, the classification identifies the analyte being measured on that individual microsphere. As the microsphere passes through a green diode-pumped solid-state laser (532 nm), the fluorescence "reporter" signal (580 nm) is generated in proportion to the analyte concentration, filtered, and measured using a photomultiplier tube. Data acquisition, analysis, and reporting are performed in real time on all microsphere sets included in the MAP. A minimum of 50 individual microspheres from each unique set are analyzed and the median value of the analyte-specific, or reporter, fluorescence is logged. Using calibrators and controls of known analyte quantity, sensitive and quantitative results are achieved with precision enhanced by the redundant oversampling at each data point.

xMAP provided several key advantages over the two-dimensional planar arrays. First, consistent coating of the polystyrene microsphere surface with antibodies has been performed in the diagnostic industry for decades, so it is a reproducible technique. Microsphere coating does not suffer from the irreproducibility that plagues planar arrays. Second, the lot size for manufacturing of a microsphere array is generally in the thousands to millions of tests per lot. Lower lot-to-lot variability coupled with extremely large manufacturing lots means that the problem of lot variation is greatly diminished. The primary disadvantage of microsphere arrays is throughput, as each sample must be read in turn in the flow system. So far, no group has solved this problem be developing multiple-channel flow systems, but this is the next logical step of the technology.

## APPLICATIONS AND EXAMPLES IN DRUG DEVELOPMENT AND DIAGNOSTICS

Whether one uses planar arrays or microsphere arrays, the resulting quantitative, multiplexed data are then mined for distinctive patterns of biomarkers that indicate disease, drug toxicity or efficacy, or some other useful biochemical phenotype. We will not discuss the data mining techniques available but simply describe several examples where data mining of these complex data sets has revealed meaningful biomarker patterns. Typically, data mining is first done using traditional statistics to identify those analytes whose values are significantly different between two experimental groups. This is often done by

determining mean analyte values and applying Student's *t*-tests to determine *p*-values of significance. The next step is often to use more complex multivariate analysis tools, such as principal component analysis, for pattern recognition.

The reports of IB monitoring cited most often are related to inflammatory disease. Asthma, rheumatoid arthritis (RA), multiple sclerosis (MS), systemic lupus erythematosus (SLE), chronic obstructive pulmonary disease (COPD), and psoriasis (PS) are thought of as classic inflammatory diseases. In recent years, a host of other diseases have been found to have a significant inflammatory component. These include cardiovascular disease (CVD), central nervous system diseases such as Alzheimer disease, most infectious diseases, and various cancers [6]. IBs are thus very useful for quantifying, characterizing, and monitoring the inflammatory and anti-inflammatory components of a disease in addition to therapeutic benefits during drug trials.

Measurement of inflammatory markers is a popular application of multiplexed profiling in drug development and diagnostic efforts. The duration and pattern of cytokine and chemokine expression in serum or plasma have been the most common uses of multiplexed immunoassays. Common inflammatory mediators are often cited (e.g., TNFα, IL-1, IL-6, IL-8, MIP-1) due to the large set of publications describing the association of these classical inflammatory markers with numerous diseases, conditions, and drug treatments. Although important, other IBs that are related directly or indirectly to the disease and/or therapy in question will often add significant prognostic value to biomarker patterning efforts.

## Inflammatory Bowel Disease in a Mouse Model

Crohn disease and ulcerative colitis are chronic inflammatory diseases of the gut that cause tremendous human suffering and loss of productivity. There is a clear need for better diagnostic tools that are less invasive or costly than endoscopy and histology. Torrence et al. published a study [7] of an inflammatory bowel disease model in mouse where they identified a serum-based IB pattern using data generated from a microsphere array. These data were generated using serum samples of mice infected with *Helicobacter bilis*, which causes an inflammation in the gut. These IB patterns were then compared with those of control animals. Samples were sent to Rules-Based Medicine (RBM), Inc., Austin, Texas for biomarker analysis using their RodentMAP (http://www.rbmmaps.com). RBM has an automated testing laboratory that utilizes xMAP technology under regulatory compliance to both good laboratory practices (GLPs) and the Clinical Laboratory Improvement Act (CLIA). RBM performed a multianalyte profile consisting of 58 different quantitative immunoassays and reported the data for each analyte in mass per milliliter of sample.

Results indicated that serum levels of IL-11, IL-17, interferon gamma-inducible protein (IP-10), lymphotactin, monocyte chemoattractant protein

(MCP-1), and vascular cell adhesion molecule (VCAM-1) were elevated in early disease. In later, more severe disease, IL-11, IP-10, haptoglobin, matrix metalloproteinase-9 (MMP-9), macrophage inhibitory protein 1 alpha (MIP 1α), fibrinogen, immunoglobulin A, apolipoprotein A1, and IL-18 were elevated. All of these biomarkers are considered IBs with the exception of apolipoprotein A1, which is considered a metabolic biomarker. Interestingly, all of the IBs correlated with histopathological scores. Antibiotic treatment of the infected mice both improved the histopathology scores and decreased the mean serum values for most of the IBs. These data suggest that the serum IB patterns could be useful for both diagnosis and prognosis of similar human diseases.

## Scleroderma

Scleroderma is an autoimmune disease that manifests itself in the skin, resulting in fibrosis and damage to the vasculature. It is thought that IBs play a major role in the course of the disease and therefore should be good targets for both therapeutic intervention and diagnostic/prognostic development. Recently, Duan et al. [8] have compared the serum IB patterns of scleroderma patients with controls using the RBM testing approach, measuring 188 different biomarkers. In addition, this group compared the serum protein expression patterns with the messenger RNA expression from the monocytes and lymphocytes isolated from these patients' peripheral blood.

As in the previous mouse study, the majority of biomarkers that were differentially expressed were IBs. Acute-phase reactants (fibrinogen, haptoglobin, and von Willebrand factor), cytokines (IL-1α, IL-16, soluble tumor necrosis factor receptor 2, and MIP-1α), tissue remodeling proteins (intercellular adhesion molecule type 1 and tissue inhibitor of metalloproteinase type 1), and one metabolic biomarker, apolipoprotein CIII, were all elevated in the scleroderma patient sera compared with normal age-matched controls. Comparison of the gene expression patterns from the various immune cell populations correlated poorly with the serum IB profiling data. This was not surprising, as these two profiles often do not correlate well. The reason(s) for the gene expression and IB profiling differences are unknown.

Results indicated that the pattern of IB elevation in scleroderma could be used as a more specific diagnostic to help the rheumatologist differentiate scleroderma from other autoimmune conditions or skin maladies. More important, the intensity of IB elevation could be used to monitor therapeutic intervention in clinical trials as well as after drugs developed for this indication are approved.

## Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an autoimmune disease where the current focus of drug development efforts is devoted to specific blockade of certain cytokine

activities. It is therefore highly likely that IB monitoring will play an important role in RA disease prognosis and drug development programs. A brief review of the cytokine blockade strategies for RA starts with the inflammatory cytokine TNFα, a major therapeutic advancement in the treatment of RA [9]. There are now several TNFα biological drugs on the market (Humira, Abbott; Enbrel, Amgen; Remicade, Centicor) that in addition to treatment of RA, are also being used off-label for psoriasis and for Crohn disease.

Blockade of IL-1 is another option available for RA therapy. Anakinra (Kineret, Amgen), a recombinant interleukin-1 receptor antagonist, is used for treatment of rheumatoid arthritis. The next major advancement in anticytokine therapy for RA appears to be the humanized anti-IL-6 receptor blocking antibody tocilizumab (Actemra, Roche). The acute-phase reactant serum amyloid A was identified in a serum profile that differentiated response from no response to Actemra therapy [10]. Intervention of IL-15 also looks promising for treatment of RA and psoriatic arthritis in addition to pulmonary inflammatory diseases [11]. Targeted cytokine neutralization as a therapeutic option in autoimmune diseases such as RA will probably lead to novel IB patterns with both prognostic and diagnostic value during drug efficacy trials. For example, in a recent study of Sjögren syndrome, a panel of 25 IBs provided diagnosis and disease management in this debilitating condition [12].

## Cardiovascular Disease

Over the past 25 years, the number of risk factors for coronary artery disease has increased dramatically. Systemic inflammation and abnormal lipoprotein metabolism are important contributors to the progression of atherosclerotic disease leading to plaque instability [13]. Even so, the vast majority of patients who experience an acute coronary event have no prior symptoms. Further complicating the diagnosis of acute coronary syndrome (ACS) is the frequent occurrence of patients who present symptoms of chest pain that can be attributable to other completely nonrelated events, such as acute gastroesophageal reflux disease. Given the serious life-threatening nature of ACS, an improvement in the early diagnosis of heart attacks would be a major medical advancement.

Matrix metalloproteinases (MMPs) are promising IBs for early identification of high-risk patients. Pro-inflammatory cytokines stimulate the secretion of MMPs, and an increase in systemic MMPs has been documented in ACS and correlated to unstable plaque metabolism [13]. In a recent study by Gurbel and co-workers, MMP-2, MMP-3, and MMP-9 were sensitive and specific markers differentiating asymptomatic coronary artery disease (A-CAD) from symptomatic CAD (S-CAD). The stable quiescent disease group of A-CAD patients were documented by angiography, a history of coronary artery bypass grafting, or revascularization (stenting or balloon angioplasty). The progressive S-CAD group of patients were enrolled immediately before coronary intervention and presented either myocardial infarction or stable angina.

Patients with S-CAD had markedly elevated levels of specific MMP-2 and MMP-9, whereas patients with A-CAD had significantly greater levels of MMP-3. In addition to the MMPs, other IBs (TIMP-1, C-reactive protein IL-8, IL-10, RANTES, endothelin, plasminogen activator inhibitor type 1, apolipoprotein C-III, and IL-1a) reinforced the MMP results for distinguishing the two groups [13].

### Hepatitis C

Wright and co-workers documented cytokine profiles of patients grouped based on their viral titers before and after standard therapy [14]. They found that they were able to demonstrate the prognostic power of serum cytokine profiling in chronic hepatitis C virus (HCV) infection. The study demonstrated that overall serum cytokine levels were significantly higher in patients than in controls and that the levels dropped significantly after therapy in concert with their viral titer. Distinct cohort subgroups based on changes in viral titers correlated to specific sets of cytokines that decreased in each group. This could allow for new efforts to stratify patients and increase efforts to find improved therapies.

### Ovarian Cancer

Ovarian cancer has been called the silent killer, as it is often not diagnosed until late in the disease progression, when therapeutic intervention is rarely successful. The unmet medical need for a sensitive and specific diagnostic test that will detect early-stage ovarian cancer and differentiate it from benign ovarian disease is strong. Bertenshaw et al. recently reported the identification of a biomarker pattern of eight serum analytes that using a multivariate algorithm could differentiate stage 2 ovarian cancer patients from benign ovarian disease [15]. In addition to *Cancer Antigen (CA)-125*, seven IBs were identified (C-reactive protein, epidermal growth factor, IL-10, IL-8, connective tissue growth factor, haptoglobin, and MMP-1) as being of importance to a potential diagnostic. These IBs, as well as *CA-125*, were identified by comparing the plasma biomarker patterns of samples from ovarian cancers in various stages, common benign gynecological conditions, as well as age-matched normal controls.

## EMERGING PARADIGM: EX VIVO IMMUNE BIOMARKER MONITORING WITH WHOLE-BLOOD CELL CULTURES

A fortuitous aspect of applying measurement proteomics to the immune system is the relative ease with which many properties of the immune system can be quantified outside the human body, ex vivo. (Herein, *ex vivo* refers to

the in vitro culture and ex vivo analysis of the immune system outside the body.) Both innate and adaptive immune system responses in blood leukocytes can be measured with multiplex IB measurements. Indeed, much of our understanding of the immune system has been generated by experimentation on human leukocytes cultures ex vivo. Given the complexity of all the different types of immune cells present in blood, a reductionist approach of isolating subpopulations of leukocytes was invaluable. For example, density gradient centrifugation of blood to obtain peripheral blood mononuclear cells (PBMCs) is a common procedure to obtain cell populations enriched for lymphocytes and monocytes but depleted of granulocytes, platelets, and red blood cells [16].

The implementation of ex vivo analysis of the immune system has only recently been deployed in the clinical drug development setting with the primary applications of safety (immunotoxicity) and pharmacodynamics. An example of an immunotoxicity application would be the Tegenero incident of 2006, in which the CD28 superagonistic antibody *TGN1412* was administered to healthy phase I volunteers. Within a few hours, a single intravenous dose induced severe lymphopenia and a systemic cytokine storm, leading to multiorgan failure [17]. Clearly, it is preferable to identify the potential for such a catastrophic drug effect during an ex vivo study. An example of a pharmacocynamic application would be quantifying IBs in the culture media that correlate with the drug mechanism of action.

The utility of ex vivo analysis of the immune system for drug development programs can be divided into two broad categories. Initially, a candidate drug can be tested ex vivo for its effects on the immune system in a resting inactivated state in addition to an activated state created by the addition of an immune stimulant to mimic inflammation. Later in the drug development process, a candidate drug can be tested in vivo in a trial subject, and the subject's immune system tested ex vivo with and without immune stimulation.

Unfortunately, the historic research methodology of utilizing PBMCs for ex vivo studies is not very adaptable to the clinical setting, nor does it provide a physiologically relevant situation for drug development studies. Compared to isolated PBMC cultures, the whole-blood culture approach has a major advantage, due to the fact that all components of the blood, including cellular (e.g., granulocytes: neutrophils, basophils, eosinophils; lymphocytes, monocytes, NK-cells), pseudocellular (e.g., red blood cells, platelets), or subcellular components (e.g., enzyme inhibitors, complement system, kininogens), are present. Therefore, functional assays performed with a whole-blood culture reflect the situation of a person's whole immune repertoire much better than do PBMC-based cultures [18–20]. In a whole-blood stimulation assay, the leukocytes are within the center of a well-composed concert of regulatory components that relies on an entire series of feedback loops, which modulate in a positive or negative manner the function of the immune system. T-cells, for example, can amplify the activities of monocytes and macrophages, and platelets produce and release precursors of leukotrienes, which are taken up

and processed further to become full-fledged mediators by polymorphonuclear granulocytes [21,22].

Red blood cells, which are not present in PBMC preparations, can produce leukotrienes and modulate the action of chemokines by expressing receptors for chemokines on their surface [23]. Plasma proteins like the complement system and the kininogens form readily available precursors of peptides exhibiting strong immunoregulating activities [24]. Some of these precursors are cleaved to become active only in the presence of enzymes, released for example by activated polymorphonuclear granulocytes [25].

Using whole-blood cultures, the functionality of the human immune system can be analyzed as close as possible to the in vivo situation. The difficulty with implementing whole-blood cultures in the clinical setting is the need for a specialized cell culture laboratory and highly trained technicians, a very expensive prospect. Shipping samples to a centralized cell culture facility dramatically reduces the quality and reproducibility of results. Recently, a standardized, fully closed, whole-blood culture system has been developed for the clinical setting that does not require cell culture facilities or specialized personnel [26,27]. The TruCulture system incorporates a 3-mL blood collection tube with cell culture media to which test substances can be added. Blood is drawn from a subject directly into a collection tube that contains a medium for an immediate and standardized initiation of the whole-blood culture. After incubation in a 37 °C heating block, the cells are physically separated from the culture medium by insertion of a valve separator, and the unit is frozen until IBs in the culture medium can be analyzed. This system will greatly aid the routine implementation of ex vivo immune monitoring in clinical trials.

## CONCLUSIONS

History has shown repeatedly that the application of a new breakthrough technology is the driving force into the next phase of meaningful discovery. The development and commercialization of quantitative multiplexed immunoassay platforms is a prime example. The two primary array platforms, planar and microsphere, provide investigators with more comprehensive biomarker data for multiple analytes with the same sensitivity and precision of single-plex testing. The technology has been invaluable to basic research and drug discovery efforts and is now moving rapidly into the clinical arena of drug development, with the goal that useful biomarker patterns will allow more informed drug development decisions to be made.

Immune-related biomarker patterning has great potential to improve the success rate of drug approval in a highly cost-effective manner. The efficiency of simultaneous profiling of multiple immune-related biomarkers with very small sample volumes has revolutionized our ability to discover and validate biomarker patterns in order to stratify patients and find markers of efficacy and safety. Central to many diseases are the immune-related biomarkers dis-

cussed in this chapter. Their modulation as drug targets themselves has also become a core theme for many of the autoimmune diseases. Finally, innovative products designed for the clinical trial setting, such as the TruCulture whole-blood culture system, will help bring immune-related biomarker patterning into the everyday realm of clinical drug development and companion diagnostics.

# GENE EXPRESSION PROFILES AS PRECLINICAL AND CLINICAL CANCER BIOMARKERS OF PROGNOSIS, DRUG RESPONSE, AND DRUG TOXICITY

Jason A. Sprowl, Ph.D., and Amadeo M. Parissenti, Ph.D.
*Laurentian University, Sudbury, Ontario, Canada*

## INTRODUCTION

Measurement of the expression level of specific genetic or protein biomarkers in patient serum or biopsies can be extremely valuable in the diagnosis and treatment of a variety of human neoplasms. Often, the careful and time-consuming evaluation of several biomarkers by highly trained pathologists is required to construct a definitive diagnosis and treatment regimen. The expression level of single or several biomarkers can also be useful in the prediction of patient prognosis or response to chemotherapy, but these approaches generally have only limited accuracy [1–4]. Current studies suggest that no single biomarker will suffice for the accurate prediction of patient prognosis or tumor response to chemotherapy [5–7]. It is therefore thought that the tumor or serum level of large groups of proteins or transcripts is necessary to predict patient prognosis or outcome reliably after chemotherapy. In this chapter we review the current progress that has been achieved in the use of gene profiling to predict patient prognosis and response or toxicity to specific

chemotherapy regimens. Moreover, the impact of experimental design and the approach to data analysis on the ability of gene profiling experiments to reliably identify large groups of genes that can serve as prognostic or predictive biomarkers is discussed. A critical assessment of the prospect for gene profiling experiments to affect the clinical management of cancer patients and drug development is also provided.

## PLATFORMS AND TOOLS FOR GENOME PROFILING EXPERIMENTS

The task of gene expression profiling is complex, and knowledge of the platforms and tools used to accomplish such a task is essential. The most popular approaches for profiling of gene expression in biological samples are DNA microarray analysis and quantitative reverse-transcription polymerase chain reaction (Q-PCR). In a typical microarray experiment (reviewed by Villeneuve and Parissenti [8]), RNA is isolated from cells, and mRNAs present within the sample are reverse-transcribed with oligo-dT primers in the presence of fluorescent or radioactive-labeled nucleotides to yield a series of labeled cDNA probes. After denaturation, the labeled cDNA probes are hybridized to known denatured PCR products or single-stranded oligonucleotides immobilized in a grid pattern on either glass slides or nylon membranes. After washing to remove unbound probe, the intensity of label associated with the various PCR products or oligonucleotides on the array can be quantified by autoradiography or by using an array scanner. The amount of labeled cDNA hybridizing to a specific gene on the microarray is a measure of its expression (level of transcription). Often, two samples can be compared for differences in gene expression by labeling the cDNA preparations from the two samples with nucleotides conjugated to dyes that fluoresce at different wavelengths (e.g., Cy3 and Cy5 dyes). In addition, cDNAs can be transcribed using three wild-type nucleotides and one aminoallyl-labeled ribonucleotide to generate labeled aminoallyl RNAs as probes [9]. While many investigators use microarrays that are prepared within their laboratories [10–13], a variety of companies now produce microarrays with widely varying numbers of oligonucleotides or PCR products immobilized to them. This creates significant variability across experiments. The oligonucleotides can also be immobilized on microarrays via different methods, including photolithography (Affymetrix) or by printing directly on glass slides. This introduces additional variability in microarray data across laboratories, resulting in significant difficulty in identifying common genetic profiles across experiments. Moreover, while standards for the performance of microarray experiments have been established (minimal information about microarray experiments (MIAME) standards [14]), not all microarray studies follow these standards.

Some genome profiling studies are also conducted using high-throughput Q-PCR. This approach is highly quantitative, providing a more reliable

measure of gene expression, but the number of genes that can be quantified is limited, since two gene-specific primers are required for each gene whose expression is measured. In addition, gene expression is measured relative to specific reference genes whose expression must also be measured. The choice of reference genes also varies significantly between studies. *Multiplexing* of reactions, and approaches in which each PCR reaction product has a distinct wavelength for fluorescence emission (e.g., the Luminex system), have helped increase the number of genes whose expression can be profiled by PCR-based approaches. PCR-based methods of genome profiling are quite distinct from those used in microarray analyses, making comparisons between Q-PCR- and microarray-based findings more difficult. Nevertheless, various PCR-based gene profiling methods have been used to identify sets of genes associated with response to chemotherapy or recurrence of disease post-chemotherapy [15–17].

## DATA ANALYSIS PITFALLS ASSOCIATED WITH GENE PROFILING EXPERIMENTS

Other difficulties in comparing data across genome profiling experiments relate to the large genetic variation that exists in humans, the design of microarray or Q-PCR experiments, and the widely varying approaches used to analyze data from such experiments. This is particularly the case for DNA microarray studies. While microarray and, in particular, PCR-based analyses are capable of measuring the expression of a large number of genes with acceptable accuracy, gene expression varies widely across patients as well as in the same person over time. In addition, the probability of identifying genes correlating with a specific phenomenon such as chemotherapy drug response is very high when tens of thousands of genes are surveyed. Unfortunately, such correlations are often not replicated in additional independent data sets, suggesting that the false discovery rate is quite high using these approaches. The use of multiple replicate arrays per sample in microarray experiments helps considerably to reduce the false discovery rate, as does the use of multiple independent data sets from highly controlled experiments.

In addition to variable gene expression among individuals, microarray procedures often yield noisy data sets with differing efficiencies of labeling and background labeling across arrays. Therefore, a variety of algorithms and statistical approaches have been developed to normalize and analyze microarray data to improve the accuracy of identifying significant changes in gene expression between groups. Statistical tests include the computation of *t*-tests for each gene and/or the use of SAM, a significance analysis for microarrays algorithm that permits one to identify significant changes in gene expression after a statistical computation of a false discovery rate based on the data set. Common additional algorithms used for microarray data analysis include weighted voting (WV) [16,18,19], supporting vector machine (SVM) [16,20,21],

and *k*-nearest-neighbor (K-NN) [16,22]. The resulting list of differentially expressed genes is commonly quite large, and each gene in this training set should then be validated by several methods, including a "leave-one-out" cross-validation. This involves the removal of one patient sample from the training set and determining if the remaining gene set is capable of classifying correctly the left-out sample. Once the training set has demonstrated accurate prediction within the samples from which it was derived, the genetic profile should be further tested within a large patient population, ideally outside of that used to create the training set. Should the genetic profile result continuously in high predictability in the classification of interest, useful sets of biomarkers have been established. However, the use of varying data analysis methods can often result in completely different sets of differentially expressed genes. Consequently, multiple data analysis techniques should be used to obtain a list of genes commonly identified across methods [23–25]. These differences in gene expression can be further validated using other independent approaches, such as Q-PCR and immunoblotting experiments.

In addition to the data analysis tools above, clustering algorithms are being used routinely to identify sets of genes whose expression is significantly and consistently different between various groups of patients (e.g., between responders and nonresponders of chemotherapy). However, it is important to note that recent findings suggest that unsupervised methods of data analysis, such as data clustering, are often not effective in identifying predictive or prognostic biomarkers. The reason for this may be that cluster analysis does not utilize information related to the original sample grouping, and it is therefore a subjective strategy for data analysis. Furthermore, the number of genes that distinguish between classifications with the use of clustering algorithms is often small, and the distances calculated in cluster analysis may not properly portray the importance of certain genes, while excluding others of great importance [26].

## GENE PROFILES AS BIOMARKERS FOR THE DIAGNOSIS AND CLASSIFICATION OF HUMAN CANCERS

Gene profiling has proven quite valuable in identifying genes whose expression can be used to diagnose specific cancers, including many that are difficult to distinguish by other methods. For example, Kohlman et al. in 2003 used gene profiling to differentiate between acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) [18]. Bone marrow samples were isolated from 90 patients, 25 having been diagnosed with ALL, and 65 with AML. RNA was extracted from the samples and labeled cDNAs hybridized to Affymetrix U95Av2 and U133 microarrays. The WV algorithm and the leave-one-out cross-validation approach were then used to identify a subset of genes that were expressed differentially between the two leukemias. The expression of 24 genes was then used to accurately identify patients with AML, while 19

genes were sufficient to diagnose ALL. However, upon comparing the genes identified by the two types of microarrays, it was observed that the 24 genes identified by the U133 arrays were different from those identified by U95Av2 chips. Furthermore, only five genes were observed to be in common within the 19-gene set when the two types of array tools were used. These results show the importance of using the same array platforms when comparing across experiments.

The utility of the U133 arrays was studied further in the diagnosis of leukemia using 937 patients (892 with clinically relevant leukemia subtypes and 45 nonleukemic patients) [27]. Patients were divided into 13 subgroups of leukemia type, and each subgroup was split equally into training and validation sets. Class-specific gene expression was determined using an SVM approach, with an overall classification accuracy of 95.1% when the top 100 genes for leukemia class discrimination were used. The studies cited above clearly demonstrate the utility of gene profiling for the diagnosis of cancers and suggest that this approach can be used further in the classification of cancers into various subgroups. Sørlie et al.'s study in 2001 further illustrates the latter utility by demonstrating that breast cancers could be classified into a basal epithelial-like group, an *ERBB2*-overexpressing group, a normal breastlike group, and a luminal epithelial/estrogen receptor–positive group, which could be further divided into at least two additional subgroups, each with a distinct gene expression profile. Interestingly, survival analyses using a subset of uniformly treated patients with locally advanced breast cancer revealed clear differences in outcomes among the various groups. For example, the basal-like group had a poor prognosis, and the two estrogen receptor–positive groups had clear differences in treatment outcome [28]. These findings have been well corroborated in additional experiments performed across array platforms and using RNA extracted from paraffin-embedded tissues [29–31]. Similar approaches and findings have been observed for endometrial cancer, hepatocellular carcinoma, sarcomas, neuroblastoma, and other cancers [32–35].

## GENE PROFILES AS BIOMARKERS OF PROGNOSIS IN CANCER PATIENTS

Despite the problems associated with gene profiling approaches that were noted above, there have recently been significant advances in using gene profiling to predict prognosis in cancer patients. For example, van't Veer and colleagues isolated at diagnosis 78 core samples from breast cancer patients under the age of 55 [36]. Of these patients, all were lymph node–free at the time of diagnosis. By measuring patient outcome over five years (regardless of treatment regimen), it was observed that 34 patients developed distant metastases, whereas 44 patients did not. Microarrays containing 25,000 human genes were prepared by the investigators, to which labeled cDNA samples from the patients and a pooled reference RNA sample were hybridized.

Following supervised data analysis and correct classification by a leave-one-out cross-validation approach, a classifier of 70 genes was developed in which disease outcome could be predicted. When used within the 78-patient sample training set, the genetic profile predicted patient outcome with an accuracy of 83%. In support of the classifier, the 70-gene set predicted with 89% accuracy the prognosis of an additional 19 patients who were not included within the training set.

The utility of the van't Veer genes as prognostic biomarkers has been tested further using a larger study, which included 295 patients [13]. Sixty-one patient samples (from the study in which the 70-gene classifier was developed) were included as a control. Of the patients used, 151 were lymph node–negative and 144 were lymph node–positive. Kaplan–Meier analysis was performed to determine the probability of patients remaining metastatis-free. The 70-gene classifier showed excellent accuracy at predicting prognosis in all patients ($p < 0.001$), including lymph node–negative patients (which generally have better outcomes). These findings further suggested that the acquisition of metastases in patients is already defined through gene expression in their tumors rather than being acquired late during tumorgenesis. The findings from the two studies clearly indicate that the 70-gene classifier can reliably predict prognosis in breast cancer patients and therefore may be useful in preventing overtreatment in some patients while identifying those that would probably benefit from adjuvant therapy [13]. The 70-gene set (also known as MammaPrint) has recently been approved for use in the United States by the Food and Drug Administration (FDA). The utility of the van't Veer classifier in predicting prognosis for cancers of tissue origins other than breast is currently unknown.

A recent investigation attempted to predict outcome in breast cancer patients using RNA from tumors of 162 patients [11] and from several cell lines to serve as the reference RNA (SW872, WM115, NTERA2, MCF-7, HEPG2, MOLT4, Hs578t, HL60, OVCAR3, COLO205, and RPMI 8226 cells). Both labeled reference and tumor RNAs were hybridized to arrays consisting of 10,368 unique genes. Analysis of the hybridized arrays by SAM, prediction analysis for microarrays (PAM), and the approaches described in the van't Veer et al. study [36] resulted in the identification of 49 genes that correlated with patient outcome. The gene list, when further reduced to 21 genes by including only those genes observed in all three analyses, displayed 69% accuracy by the leave-one-out cross-validation strategy. Using the gene set, the classifier appeared to predict patient outcome with 65% accuracy using the van't Veer data and 62% accuracy using data from another study [37]. Considering chance alone can yield as much as 60% accuracy; the gene set above was not validated. Furthermore, the expression of the van't Veer prognostic genes was unable to classify the patients successfully in terms of disease outcome, though over half of the genes identified in the van't Veer study were not present on the microarrays used. This underscores the difficulties in comparing across microarray experiments when different array platforms are used.

In addition, successful prediction of prognosis using this subset of the 70-gene classifier may have been increased by dividing patients according to lymph node status as was done in the van't Veer follow-up study [13].

While the van't Veer classifier shows significant promise, it has yet to be used widely in a clinical setting. An alternative gene classifier has undergone considerable validation in a clinical setting. This classifier was developed by selecting 250 candidate genes that showed promise as prognostic biomarkers, based on literature searches and previous microarray experiments [13,19,28,38]. The expression of these genes was then measured in tumor biopsies of 447 patients associated with three independent clinical trials. Analysis of the relationship between the tumor expression of each gene and patient outcome resulted in the identification of 21 prognostic genes, including 16 cancer-related genes and five reference genes. This 21-gene prognostic classifier is now known as the Oncotype DX profile [15]. Interestingly, five of the 16 genes in the Oncotype DX profile were identified previously in the study by van't Veer et al. [36]. The Oncotype DX genetic profile measures the probability of disease recurrence in patients diagnosed with estrogen receptor–positive, lymph node–negative breast cancer who were treated with tamoxifen. The likelihood of recurrence is measured using a recurrence score, which is calculated by measuring the expression of the 21 genes and converts these values into a score ranging from 1 to 100. Low risk of recurrence is determined by a score of <18, while ranges from 18 to 30 and ≥31 indicates intermediate and high risk of recurrence, respectively. The Oncotype DX gene set has been validated in three additional clinical trials [15,39,40] and is currently undergoing further validation in a phase III study known as TAILORx. Furthermore, the Oncotype DX gene set has been studied further for its ability to predict factors other than disease recurrence. The recurrence score was recently used to measure recurrence risk in 651 patients who were randomly assigned to treatment with tamoxifen or tamoxifen and chemotherapy [41]. The 10-year distant recurrence rates were determined for the two treatment groups and it was revealed that low- and intermediate-risk patients (as predicted by RS) did not benefit from chemotherapy. In contrast, high-risk patients derived great benefit from chemotherapy. Therefore, the Oncotype DX recurrence score appears capable of identifying in a group of patients who typically have a relatively low risk of disease recurrence those who will probably benefit from chemotherapy. This, in turn, would enable us to spend health care resources more efficiently by providing chemotherapy only to those who will benefit from treatment.

## CLASSIFICATION OF TOXINS AND PREDICTION OF DRUG TOXICITY USING GENE EXPRESSION PROFILING

Profiling of gene expression in cells is not limited to the diagnosis, classification, or prognosis of disease. One can also profile changes in gene expression

elicited by external agents such as chemotherapy drugs or toxicants. This can provide significant insight into their mechanisms of action. It is theorized that certain families of drugs or toxicants induce similar changes in gene expression in various cell lines, such that gene expression profiles or *signatures* can be used to classify known and unknown drugs or toxicants.

Nuwaysir and colleagues reviewed the potential utility of microarrays in the identification, classification, and characterization of toxicants in toxicology studies [42]. The authors suggested a procedure involving the treatment of specific cell lines or animals with or without a known toxicant, isolation of RNA from the cell lines or animal organs, reverse transcription of the RNAs to create differentially labeled cDNAs, and the profiling of gene expression by microarray analysis. The use of toxicants of a specific class with a known mechanism of action in gene profiling experiments would then allow researchers reliably to identify changes in gene expression associated with a known class of toxicant (a *toxicant signature*). After a wide variety of toxicant signatures have been established for known toxicants, the toxicant signature for an unknown toxicant could be established and compared to standard toxicant signatures in order to identify and/or classify the unknown toxicant. Moreover, the toxicant signature could provide significant insight into the biochemical mechanisms responsible for its toxicity. Nuwaysir et al. further discussed how microarray technology could be used in toxicology studies involving animal models [42]. Current methods of toxicology measure toxin levels or the expression of specific hepatic enzymes levels within blood [42,43]. The use of animal models often requires that studies take place over an extensive period of time, particularly for chronic exposure to low levels of toxins. In contrast, gene expression changes typically occur quickly (in the manner of hours) and may require only low levels of toxicants. Therefore, specific posttreatment changes in gene expression may be effective measures of exposure to certain toxicants and may provide insight both into the mechanism of toxicity and into effective measures to combat this toxicity. As raised by Nuwaysir and colleagues [42], specific standards would have to be established, including the animal model to be used, the organs to be assessed for changes in gene expression, the concentration of compounds to be administered, and the time following exposure when gene expression will be measured. Such factors will probably be dependent on the toxicant, its properties, and its target organ. Other influences on the degree of toxicity and on gene expression would also have to be minimized, including the age of subjects or animals, variations in diet, and gender.

Recently, there have been several attempts to use the approach described above to identify changes in gene expression associated with exposure to known hepatotoxic or nephrotoxic compounds in either human or animal models. Fielden et al. [44] used gene profiling approaches in rats to identify changes in gene expression induced by nephrotoxic agents, after confirmation of renal tubular degeneration by histopathology. By identifying gene profiles associated with the onset of nephrotoxicity in rats, these authors theorized

that drug development could be strongly facilitated by focusing on lead compounds that, when profiled, did not exhibit nephrotoxicity-associated changes in gene expression. In the study, rats were subjected to short, repeated exposures to well-classified toxicants or the vehicle in which they were dissolved. Changes in gene expression induced in the rats by 15 nephrotoxic and 49 nonnephrotoxic compounds were then studied by microarray analysis. Blood samples were assessed for changes in cholesterol or albumin levels, which would be consistent with the onset of nephrotoxicity. Rats were only sacrificed upon detection of nephrotoxicity-associated changes in blood levels of cholesterol or albumin. RNA was isolated from kidneys, and toxicant-induced changes in gene expression were determined for these compounds by cDNA microarray analysis using Amersham Codelink Uniset Rat1 Bioarrays and the sparse linear programming (SPLP) algorithm. Thirty-five genes were identified as changing expression only upon administration of nephrotoxic compounds to rats. Interestingly, within the training set, the 35-gene classifier was found to have 83% accuracy for identifying nephrotoxic compounds with renal tubular degeneration and 94% accuracy for identification of compounds that are not nephrotoxic. Studies were then conducted for cross-validation of the classifier with an additional 21 independent rodent samples. In the validation experiments, nephrotoxic agents were identified with 79% accuracy and nonnephrotoxic samples with 75% accuracy. Although complete accuracy at identifying nephrotoxic agents was not obtained, this approach would nevertheless help in drug discovery programs to eliminate lead compounds that have a significantly higher likelihood of being nephrotoxic. However, the identity of the 35 genes did not provide significant insight into likely mechanisms for nephrotoxicity. It is also unknown whether the gene expression changes identified in rats were specific to kidney tissue. In addition, it should be noted that there are significant differences between rats and humans in terms of their metabolism of and sensitivity to drugs and toxicants. Thus, while the study did appear able to show a significant link between the expression of specific genes and nephrotoxicity, it remains unclear whether rats serve as a good model for nephrotoxicity in humans.

An attempt to address the differences in toxicant metabolism between rats and humans was addressed in a study by Martin et al. [45]. This study utilized the potential of two toxicogenomic knowledge bases to estimate the hepatotoxicity of various compounds in humans based on changes in gene expression induced by the toxic compounds within rat in vitro and in vivo models. The in vitro analysis consisted of observing through microarray analysis changes in gene expression induced by 86 compounds, 36 of which were nonhepatotoxins. In contrast, the in vivo study analyzed gene expression changes induced by 111 compounds, 32 of which were nonhepatotoxic. Affymetrix RGU34 microarrays were used containing probes for 8799 genes. Toxicant-induced changes in gene expression were identified through comparison to control cell lines or rats exposed to the solvent in which the toxicant was dissolved. Using a tree-based machine learning technique known as *gradient boosting*, 173

genes were identified whose expression would be expected to be modified by hepatotoxins in humans. In the in vivo experiments, 168 genes would be expected to change expression in humans by hepatotoxins. Unfortunately, while the in vitro and in vivo data identified real gene classifiers associated with hepatotoxicity, only five genes were identified in both the in vitro and in vivo experiments. Furthermore, none of the common genes identified were within the top 30 changes in gene expression, and validation experiments strongly suggested that both the in vitro and in vivo gene sets were found to be poor predictors of toxicity. To increase the reliability of predictive gene sets and decrease the degree of variability within the data, it is recommended that higher numbers of nontoxic compounds also be monitored for changes in gene expression (as controls) and that associated toxicology databases have better coverage of human studies.

Given the findings described above, it appears that significant additional work is required before reliable gene classifiers for the identification of nephrotoxic or hepatotoxic compounds are available. Most toxicology studies are performed in animal model systems due to ethical concerns and it appears unlikely that such studies can be extrapolated easily to humans (particularly if rodents are used). Human cell lines could be used, but such in vitro experiments are unlikely to be replicated in living human subjects. Nevertheless, the development of gene classifiers for toxicants in nonhuman systems could assist the drug discovery process by avoiding lead compounds that induce changes in gene expression in both rodents and human cell lines which resemble strongly those of known nephrotoxic and hepatotoxic compounds. In addition, gene classifiers for agents capable of inducing toxicity to other organs (e.g., cardiotoxicity) can possibly be developed using this approach.

## USE OF GENE PROFILING TO PREDICT DRUG SENSITIVITY OR RESISTANCE

Approaches similar to those described above for toxicants can also be used to classify drugs and their modes of action. Moreover, it may be possible to use genome profiling of patients to identify those that would probably benefit from administration of a particular drug. Considerable emphasis has been placed recently on the identification of genes whose expression in the tumors or host tissues of cancer patients can predict or measure the response to specific chemotherapy agents or regimens. Various families of chemotherapy drugs act by different mechanisms within tumors, such as the inhibition of topoisomerase II or DNA replication [46–49] or the stabilization of microtubules [50]. Destruction of such essential functions would be expected to trigger cell cycle checkpoints and promote cell death mechanisms, resulting in specific changes in gene expression that are characteristic to the administered drug. In addition, since tumors can often be heterogeneous, there may exist within the tumor population variants that before or after drug treatment are better able to

survive in the presence of chemotherapy agents. These or additional variants may also be capable of inactivating specific chemotherapy agents or blocking drug-induced cell death pathways. This would result in drug resistance, which is often observed in cancer patients before or after treatment with chemotherapy agents. By genome profiling of tumor or host tissues from cancer patients, it may be possible to identify which tumors or patients are likely to exhibit resistance to a given chemotherapy agent. Moreover, the genome profile may enable the oncologist to select a chemotherapy agent that has the highest probability of killing a given tumor. The profiling and classification of tumors into specific subtypes (as described above) may aid further in this goal.

Chang et al. were the first researchers to use gene profiling successfully to identify possible genes whose expression in tumors pretreatment could differentiate between responders and nonresponders of docetaxel chemotherapy [10]. Patient tumor size was measured throughout treatment, allowing classification of 24 patients into 11 responders and 13 nonresponders (who had progressive disease or no response to treatment). RNA was isolated from tumors before chemotherapy, amplified, reverse-transcribed to cDNA, labeled with Cy3 or Cy5 fluorescent dyes, and hybridized to HgU95-Av2 Affymetrix microarrays. Student's *t*-tests were used to identify 92 genes whose expression was significantly different between responders and nonresponders. Using these genes in a leave-one-out cross-validation approach, the gene set appeared to correctly classify responders and nonresponders with an accuracy of 88% within its training set. The genes identified were found to be involved in various cellular functions, such as cell signaling, immunologic response, DNA damage detection or repair, cell cycle regulation, and tumor suppressors. To confirm this gene set, the expression level of 15 differentially expressed genes was determined by reverse-transcription polymerase chain reaction. Thirteen positive correlations were obtained, of which six were found to be highly significant between responders and nonresponders. To test this genetic profile further , RNA was isolated from six additional patients who were not involved in the training set. Quantitation of expression of the 92 genes using the same approach correctly identified all six as drug responders. The accuracy of the 92-gene profile to predict response to docetaxel chemotherapy was then further evaluated in a follow-up study by the same investigators [51]. The authors observed gene expression of resistant and sensitive tumors after 3 weeks of treatment in a subset of 13 patients. Surprisingly, very few differences in gene expression were observed. Therefore, it would appear that changes in tumor gene expression shortly after administration of docetaxel cannot be used to differentiate between responding and nonresponding tumors.

A study by Iwao-Koizumi et al. also used high-throughput Q-PCR to identify genes whose expression could predict response to docetaxel in 44 breast tumors [16]. The expression of 2453 genes was profiled in the tumors relative to controlling RNA from 78 primary breast cancers. WV, K-NN, and SVM approaches were used in data analyses to identify gene sets, which were then

subjected to leave-one-out verification studies. It was observed that the most consistent results were obtained with the use of the WV algorithm, which identified 85 genes that were capable of identifying response to docetaxel with 80.7% accuracy in verification studies. To provide further evidence of their utility, expression vectors containing cDNAs for a number of the genes associated with resistance to docetaxel chemotherapy were transfected into MCF-7 cells and were found to increase survival in the presence of docetaxel compared to nontransfected controls. This suggests that observations from in vitro experiments using cell lines may have relevance to drug resistance in cancer patients. Interestingly, the genes determined to be associated with docetaxel response in this study differed greatly from those identified in the study by Chang and colleagues [10]. Only three genes were in common between the two studies. A number of differences in the studies may account for this discordance, including different patient populations, widely varying sets of genes being profiled, and differences in the algorithms used in data analysis. Use of a more quantitative method for gene profiling, the larger set of patients, and the higher prediction accuracy would suggest that the 85-gene set identified by Iwao-Koizumi has a higher probability of being replicated in other independent studies.

Genome profiling was also used by Cleator et al. to identify genes whose expression is predictive of response to doxorubicin/cyclophosphamide chemotherapy in breast cancer patients [52]. In this study, RNA samples were isolated from 12 patients whose tumors responded to chemotherapy and from six patients whose tumors did not. After amplification and labeling, the RNAs were hybridized to Affymetrix HgU133A arrays. After scanning the arrays, the output data were assessed using a "randomized variance model," and 253 genes were identified to be differentially expressed between responding and nonresponding tumors. Leave-one-out cross-validation studies were then performed using the training set, and only 67% of samples were correctly classified as responders or nonresponders. This accuracy is only slightly better than chance. Thus, this approach could not be used to identify genes associated with response to doxorubicin/cyclophosphamide chemotherapy, or, more likely, the number of patients in the training set was of insufficient size to reliably identify genetic biomarkers for prediction of response to doxorubicin/cyclophosphamide chemotherapy. The authors of this study also tested the ability of the Chang 92-gene set for docetaxel responsiveness [10] (described above) to predict response to doxorubicin/cyclophosphamide treatment. The 92-gene profile was unable to distinguish between responders and nonresponders of doxorubicin/cyclophosphamide chemotherapy, suggesting that genes for prediction of response to chemotherapy regimens are probably regimen-specific and not general biomarkers of drug response.

A similar approach to that described above was used to identify 74 genes whose expression correlates positively or negatively with response to T/FAC chemotherapy (paclitaxel, followed by 5-fluorouracil, doxorubicin, and cyclophosphamide). Accuracy at measuring response to this regimen was deter-

mined to be 78% [53]. Independent expression of any one of the 74 genes could not be used to predict response to T/FAC chemotherapy.

As mentioned previously, false discovery rates are often high in genome profiling experiments, particularly when tens of thousands of genes are surveyed. Thus, in the gene profiling studies above, the genes identified may correlate with drug response, but, in reality, may have no relationship to drug action. This would then explain the many failures that have been observed in identifying genes whose expression correlates with drug response across a wide variety of independent clinical studies. To circumvent this problem, it can often be advantageous to restrict the analysis of genes in patient populations to those that have demonstrated a clear relationship with drug response or resistance in in vitro studies. A number of studies have identified clear differences in gene expression between drug-sensitive and drug-resistant tumor cells. For example, Villeneuve et al. used microarray studies to identify a number of genes whose expression was altered in doxorubicin- or paclitaxel-resistant MCF-7 breast tumor cells compared to wild-type cells [12]. The majority of genes (>98%) exhibited no difference in expression between the wild-type and drug-resistant cell lines, confirming the isogenicity of the established cell line. One strength of this study was that 91 to 95% of the differences in gene expression identified by microarray analysis were corroborated through Q-PCR verification experiments. In addition, control cell lines were created to account for differences in gene expression during selection for drug resistance that were simply due to extended propagation of cells in culture. The identities of the genes uncovered in this study were associated with drug transport, drug metabolism, growth promotion, and cell death inhibition, consistent with the types of genes that one might expect to observe in drug-resistant cells. Thus, this approach has the prospect of providing significant insight into the many and varied mechanisms by which tumor cells acquire resistance to chemotherapy drugs.

The limitation of the study by Villeneuve et al. [12] is that gene expression was compared between single sets of isogenic wild-type and drug-resistant breast tumor cell lines. Although the genes identified may play a role in drug resistance in a single breast tumor cell line, some may have little relevance to drug resistance in other breast tumor cell lines or other cell lines of different tissue origin. In contrast, genes having altered expression in cell lines from several tissues upon acquisition of resistance to a specific drug have a higher likelihood of playing a bona fide role in drug resistance, although probably not in a tissue-specific manner. Györffy et al. profiled gene expression across 30 different cancer cell lines using HGU133 Affymetrix arrays and identified genes whose expression correlated with sensitivity or resistance to 11 different chemotherapy drugs [24]. The accuracy of the gene sets to identify a cell line as sensitive or resistant to a given chemotherapy agent was 86%. Using this approach, 1481 genes were identified as playing a role in resistance to a diverse set of anticancer agents. Not surprisingly, the drug-resistance genes identified were different depending on the chemotherapy agent. Only 67 genes were

observed to be associated with resistance to four or more anticancer agents, and the expression level of only two genes correlated with resistance to all 11 drugs. In a similar study [54], HGU133 Affymetrix arrays were also used in the study by Györffy et al. to identify genes associated with resistance in gastric cancer cells to three of the agents used. Despite similar array platforms, the number and identities of genes associated with resistance to 5-fluorouracil, doxorubicin, or cisplatin varied dramatically between the two studies. A number of factors could account for the differences in the gene numbers and identities. Whereas the former study assessed a large number of wild-type and drug-resistant cell lines of varying tissue origin for sensitivity or resistance to 11 chemotherapy agents, the latter study examined only 14 gastric cancer cell lines, of which 10 were resistant to one of three chemotherapy agents. Thus, it is possible that the genes associated with drug resistance in gastric cancer cells are distinct from those that would have relevance across cell lines. Alternatively, variations in experimental design, the number of cell lines, and approaches to microarray data analysis resulted in the identification of different gene sets, which may or may not be relevant to drug resistance.

## STRATEGIES TO IMPROVE THE ACCURACY OF GENE PROFILING IN IDENTIFYING PROGNOSTIC AND PREDICTIVE BIOMARKERS

As stated previously, very few gene sets have proven reliable in predicting response to chemotherapy agents across large groups of patients [10,11,16]. Numerous factors may contribute to the poor reproducibility of findings from gene profiling experiments, including differences in the tissues studied, the array platforms, the number and nature of genes on the microarrays, RNA extraction procedures, the number of replicate arrays used in experiments, and the data analysis and verification methods. Simon and colleagues reviewed approaches to improving the accuracy of gene profiling experiments in the identification of reliable predictive or prognostic biomarkers [26]. The first limitation to the reliable identification of predictive and prognostic biomarkers is the size of the training and validation sets, which in many studies is from 30 to 50 patients. Larger data sets of 500 patients or more have a much higher probability than small data sets of identifying useful biomarkers that can be validated across experiments. The use of more than one method for obtaining gene classifiers is also preferred. Moreover, in addition to larger data sets, there should be equal representation between patients from which the positive and negative classifiers will be developed. In addition, a number of studies only validate the utility of a gene set to positively identify patients with a particular attribute, without showing that the positive classifier has no ability to identify patients without the attribute.

Minna et al. [23] discussed further the reproducibly of genome profiling experiments across laboratories in an editorial written in response to a study

by Hsu et al. [25] which identified a set of genes that could serve as a classifier of cisplatin responsiveness. While acknowledging the promising prospects of the study by Hsu and colleagues, Minna et al. commented on what additional information could have been described or collected in this and other microarray experiments. These include the method used for classification of patients, the analytical procedures used in the genome profiling experiments, and access to *all* microarray data so that it is available for analysis by researchers. The free availability of well-described data sets will enable future researchers to use this information to identify the best analytical methods for microarray data and to compare microarray data analysis tools effectively across experiments. This will enable researchers to determine if future gene sets can accurately predict drug response in groups of patients outside the initial training and validation sets. It will also enable researchers to repeat or apply new analytical procedures to previous data sets in order to make effective comparisons across experiments. Interestingly, it has been shown that with the use of identical gene arrays, extraction methods, and statistical analyses, identical gene signatures can be obtained across microarray experiments, despite differences in operators, sample handling, and time of extraction [55].

## FUTURE DIRECTIONS

There can be little doubt that genome profiling experiments are beginning to yield important new biomarkers of clinical relevance, particularly for the diagnosis of disease states. However, considerable variability exists in the performance of genome profiling experiments across studies, in particular for microarray studies. Differences in array platforms, the number and identities of genes on arrays, sample size, experimental design, methods of patient classification and RNA extraction, and algorithms for data analysis all contribute to the wide variability observed in microarray findings. Only through comparisons across well-characterized microarray experiments can a clear conclusion be made as to the optimal design of a microarray experiment and optimal methods for both data analysis and patient classification. Moreover, by describing array experiments in detail and ensuring full access to microarray data, it should be possible to repeat microarray data analyses using such optimal methods (once defined). In the future, the preferred method of microarray experimental design and microarray data analysis will enable more accurate and reproducible findings to be achieved. This will dramatically increase the capacity of microarray studies to affect the clinical diagnosis and management of cancer patients.

Microarray or PCR-based gene profiling experiments are powerful tools which, used optimally will dramatically increase the discovery of gene classifiers for the accurate diagnosis of cancer patients and for the optimal management of their care. This would probably include gene classifiers for the prediction of patient prognosis pre- and posttherapy, the optimal selection of

chemotherapy agents, and the measurement of patient response and/or toxicity to these agents. Moreover, genome profiling is likely to have a major impact on drug discovery programs by enabling investigators to classify and characterize drugs and toxicants, with the goal of optimizing drug structures to achieve maximal therapeutic benefit with minimal toxicity to patients. Gene profiling of patients and their tumors before and after drug treatment may also enable us to tailor our approaches to the management of cancer patients by accurately identifying those that will derive benefit, with minimal toxicity, from a given chemotherapy regimen. For the pharmaceutical industry, this may also permit the introduction or reintroduction of highly effective drugs into the marketplace that exhibit toxicities in rare subsets of patients.

Recent evidence confirms that gene profiling experiments are beginning to revolutionize the practice of oncology and that physicians are prepared to embrace their use, provided that the utility of genetic biomarkers identified from gene profiling experiments are widely validated in appropriately conducted clinical trials. This appears to be the case for both Oncotype DX [15,41] and Mammaprint [56] gene sets for prediction of prognosis in women with breast cancer. The Oncotype DX gene expression assay will probably be widely used by breast oncologists for a number of reasons:

1. The recurrence score associated with the gene set used in this assay greatly aids the oncologist in assessing the prognosis of a patient and the need for adjuvant chemotherapy, such as MF/CMF [41]. This is particularly useful for low-risk patients with node-negative, ER-positive tumors, where the physician is likely to recommend adjuvant chemotherapy for patients with high recurrence scores but not for patients with low recurrence scores.
2. Respected clinical organizations such as the American Society of Clinical Oncology [57] and the National Comprehensive Cancer Network have established clear clinical guidelines for use of the Oncotype DX assay in patients with tumors of 0.6 to 1 cm with moderate to poorly differentiated or unfavorable features, and all tumors larger than 1 cm.
3. Gene expression is assessed by a highly quantitative procedure (Q-PCR) conducted centrally in a recognized laboratory following good laboratory practices (GLP) guidelines.
4. There is now evidence that an expanded Oncotype DX assay, which includes estrogen and progesterone receptor scores, provides a quantitative measure of the expression of these receptors with a high degree of concordance with standard immunohistochemical approaches [58]. This provides greater information to the physician on the degree of expression of the receptors and the confidence that can be placed on the diagnosis and treatment plans based on receptor status. Such developments further increase the adoption of this assay by breast oncologists. In addition to the benefits of the Oncotype DX assay, recent studies using the new molecular classifications of breast cancer (based on earlier genome

profiling studies) suggest that responses to specific therapies may vary significantly among the various subgroups.

Successful adoption of the Oncotype DX assay into clinical trials and into clinical practice guidelines clearly illustrates that oncologists are willing to accept quantitative gene profiling of patient tumors as an important tool in the clinical management of a cancer patient, but this requires the successful translation of findings in research laboratories into validated robust assays that can be conducted in licensed clinical service laboratories. The support and cooperation of clinical societies is critical to the adoption of gene-based assays into the clinic, including the establishment of clear practice guidelines for the physician.

# USE OF HIGH-THROUGHPUT PROTEOMIC ARRAYS FOR THE DISCOVERY OF DISEASE-ASSOCIATED MOLECULES

Douglas M. Molina, Ph.D., W. John W. Morrow, Ph.D., and Xiaowu Liang, Ph.D.
*Antigen Discovery, Inc., Irvine, California*

## INTRODUCTION

The discovery of biologically relevant disease-state markers, or biomarkers, is a crucial step in the maturation of accurate disease diagnosis and appropriate treatment. With all the advances in modern research, the need for better diagnostics as well as markers of disease is paramount. The management of infection, cancer, and autoimmune disorders could benefit greatly from new biomarkers, or combinations of biomarkers, that could provide quick and accurate identification of the causative agent of disease, disease state, and even the stage of the disease. The lack of progress in identifying such molecules is due primarily to the way that, to date, researchers have approached the problem. When using traditional approaches to the discovery of serodiagnostic antigens, researchers have been limited to the number of molecules they could study. Typically, most laboratories have studied just a handful of proteins at any given time and therefore have only a limited understanding of the pathobiology of disease. Much like the children's game *Flip 'n' Match*, inves-

tigators have employed the "best guess" approach to which "pieces" (i.e., antigens or proteins) may be most appropriate as disease markers. Such best-guess hypotheses have usually been based on the body of literature available as well as extrapolations from our understanding of the immune response. Much as in the game, once in a while the correct choice is made. However, a much more productive approach would be to view all the pieces simultaneously and assess the complete picture, without prejudice, in the context of the immune response profile. In this way we would be in a much better position to make determinations as to which proteins, or combinations of proteins, would allow us to diagnose and monitor disease accurately. Very recently, such an approach has been made possible, and in this chapter we discuss how researchers have taken advantage of the sequencing boom sparked by the human genome project. We also examine assay miniaturization technology, which has carried over from the nucleic acid microarray field, and how new advances in cloning and gene expression have allowed the use of those resources to profile the immune response to infection, cancer, and autoimmune disease.

## OVERVIEW OF THE PRODUCTION AND USE OF MICROARRAYS FOR THE DISCOVERY OF ANTIGENIC BIOMARKERS

To take advantage of genomic sequence data for the development of novel therapeutics and clinical diagnostics, high-throughput cloning and screening technologies are required. The authors and own collaborators have developed and described a gene cloning and expression platform that allows whole proteome microarrays to be constructed from genomic sequence information in a relatively short time. The platform can then be screened with large numbers of well-characterized sera to identify antibody targets. This powerful high-throughput approach lends itself to the rapid identification of reactive antigens on an epidemiological scale, and should lead to the development of improved serodiagnostic tests for many diseases (Figure 1).

## PROTEIN MICROARRAYS

In the context of the discovery of disease-associated molecules, protein microarrays can be thought of as miniaturized dot blots or highly multiplexed enzyme-linked immunosorbent assays (ELISAs) for serology, and highly multiplexed sedimentation, co-immunoprecipitation assays, or enzyme function assays for protein biochemistry. They allow data collection from hundreds of parallel interaction studies in an area the size of a single well of a 96-well ELISA plate. To achieve this type of miniaturization, the chemistry of the surface being used for spotting the proteins is important. Reagents can

be coated onto activated plastics or glass to accommodate the deposition and subsequent binding of the protein onto the surface. Some examples of the chemistries used to bind proteins to the substrates are described below.

### Two-Dimensional Substrates

Well-characterized protein-binding substrates, used extensively in other assays, have been transferred or "ported" for the use of microarray fabrication. Most of these surface substrates were used extensively in DNA microarray research and have been used with success with purified protein arrays. There are two principal ways that proteins bind to surfaces: (1) by the formation of covalent bonds with reactive groups on the surface of the slide, and (2) by noncovalent interactions with the slide substrate.

In slide surface chemistry, the use of aldehyde and epoxy coatings allows for covalent bonds between the proteins by virtue of the amine group on amino acids and the activated aldehyde of the epoxy group on the slide [1,2]. The primary amine group reacts with the aldehyde, or epoxy, groups on the slide surface. The electrons on the nitrogen attach to the carbon with a partial positive charge on the reactive group and form a nitrogen–carbon bond. In protein–aldehyde coupling, the attachment is stabilized by a dehydration reaction. Another option for two-dimensional substrates is the coat the slide surface with a molecule that is part of a high-affinity binding interaction. Binding-partner substrates are not as common but are still useful. There are examples of protein-binding surfaces that have been treated with avidin, streptavidin, glutathione, and monoclonal antitag antibodies. Unlike the aldehyde and epoxy examples, these are very specific and require that the appropriate binding partner be coupled to the protein(s) being spotted.

### Three-Dimensional Substrates

Polyacrylamide-coated slides form a three-dimensional substrate for protein microarrays. Much like the polyacrylamide gels used for electrophoresis, they are reported to provide high probe loading capacity and a hydrophilic, solution phase–like environment, which is thought to preserve protein probe function [3–6]. Consequently, this flexible and versatile platform is well suited for many types of proteins and has been used to develop a variety of assays in microarray format. A three-dimensional hydrogel coating preserves the native three-dimensional structure of proteins, thereby maintaining stability and functionality. The reactive chemistry is stable and remains active even during very long spotting (also know as "printing") runs. Agarose is an economical, protein-friendly medium that reduces the background of the slide significantly, which can interfere with signal detection of low-abundance proteins or pep-

tides. There are other proprietary three-dimensional porous polymer surfaces, such as those produced by Full Moon Biosystems, that claim to provide a high level of sensitivity and specificity for fluorescence-based assays. All seem to have similar properties, which include covalent multifunctional bonding sites that provide high binding specificity by covalent attachment to surface functional groups.

Nitrocellulose is the best-characterized protein-binding chemistry that has been adapted successfully to microarray fabrication. Nitrocellulose membranes are used for immobilizing a wide variety of molecules, such as nucleic acids in Southern and Northern blots, as well as proteins in Western blots. Nitrocellulose makes an ideal surface for a wide variety of assays, including antibody-based assays, due to its nonspecific affinity for proteins. Nitrocellulose is usually coated onto a nylon backbone to produce membranes. It has also been coated on activated glass microscope slide, and as such has become a very popular tool for the fabrication of protein microarrays. A variety of nitrocellulose-coated slides are currently available which are ideal for microarrays because of their high binding capacity per unit volume. At one end of the spectrum, the nitrocellulose surface may be as thin as 5 μm (Path Slides, GenTel), and at the other, the membrane can be as thick as 150 μm (SuperNitro, Telechem). In the case of nitrocellulose-coated slides, it is critically important to pick the correct thickness for the application. The thickness of the coating chosen will be influenced greatly by the type of microarray printing that is to be used.

## Contact vs. Noncontact Printing

Like DNA microarray fabrication, protein microarray fabrication is dependent on applying the protein onto the substrate reliably and reproducibly. To achieve this objective, two major classes of spotting, or microarray printing, have evolved. Noncontact printing is the mechanism of spotting onto the slide or plate surface without any contact. The volumes range from picoliters up to hundreds of microliters having coefficients of variation (CVs) of less than 10%, depending on the technology used. One such technology, solenoid-based dispensing systems, relies on the rapid opening and closing of valves, which permits the flow of pressurized liquid. Rapid opening and closing of a valve, or pulsing, results in a very small volume being deposited. Leaving the valve open longer results in the deposition of larger volumes. Solenoid-based systems typically spot between 10 nl and hundreds of microliters. Another noncontact technology, piezoelectric-based dispensing systems, can dispense as little as picoliter quantities of liquid. They rely on electrical pulses that create a pressure wave when a piezoelectric element is deformed and squeezes the tubing, the pressure created results in the displacement of a small volume of liquid. By opening the valve at the precise moment that the piezoelectric element is deformed, a small volume of liquid is deposited on the substrate.

The main drawback of noncontact printing is that it is not the ideal tool for arraying more viscous or concentrated protein mixtures. Cell lysates immediately come to mind when considering heterogeneous materials that may cause problems for noncontact arrayers. There is a high potential for clogging not only the dispensing solenoids, but the tubing as well. Another drawback is that the noncontact dispensing robots available are limited by the number of valves that can be used to array spots onto a slide or plate; thus, throughput becomes a problem. When printing thousands of different samples, the number of solenoids becomes the limiting step.

Contact printers address these shortcomings directly. Although there are numerous variants of contact printing technologies, the two most prevalent are the solid pin and split pin methods. Unlike the solenoid- and valve-based systems, pin-based printing systems are not limited by size. Some printers use the traditional 9-mm pin spacing used in 96-well microtiter plates, but the majority use 4.5-mm pin spacing. More recently, printers that use 2.25-mm pin spacing have become available. Depending on the size of the printhead, as many as 256 pins in an $8 \times 32$ configuration can be fitted when the 2.25-mm spacing is used. This results in 256 samples for every sample uptake, or over 1000 samples with only four sample uptakes. The basics are the same in solid pin and split pin printing. The robot dips the pins into the samples, the pins deposit the sample on a substrate by making contact, the pins re-dip when necessary, and the pins are washed before the next sample. Solid pins must re-dip after every deposit on a substrate; split pins act more like a quill and fill up a reservoir, of which only a fraction is deposited every time the pins make contact.

The number of spots that can be made after sample uptake by split pins varies greatly depending on a number of factors. The viscosity of the sample, the substrate type due to varying amounts of adsorption, the humidity, the pin design, and whether or not it has a reservoir are all factors and must be tested for empirically. When making DNA arrays, the samples are more homogeneous; they have similar viscosities, similar concentrations (moles of DNA), and similar molecule substrate interactions. When dealing with protein microarrays these characteristics are seldom the same. Proteins are usually dialyzed after purification with whichever buffer will keep the protein in solution. This can very widely from protein to protein. This will contribute to potential viscosity differences. Protein concentrations can vary greatly depending on the success of expression and subsequent purification of the protein. In case the concentrations are similar, proteins vary in size and there will be a heterogeneous distribution of the number of molecules per spot. The amino acid sequence of the protein(s) will also influence how it interacts with the substrate on which it is being spotted. In addition, the isoelectric point of the proteins will undoubtedly have an effect on how they bind to the substrate, and furthermore, hydrophilic proteins will behave differently than hydrophobic proteins. There is also the problem of protein aggregation, or too high a concentration, clogging a split pin. There are various-sized split pins with chan-

nels up to 400 μm across which would accommodate most substances. As attempts to make higher-density arrays to increase throughput take place, this option become less feasible.

When the substrate to be arrayed is not compatible with the split pins necessary to meet the array density required, solid pins must be employed. The need for solid pins is more of an issue when arraying cell lysates, cells of bacterial culture fractions. Solid pins are a better choice for these situations, but at the expense of throughput. Even the fastest solid pin machine, the Aushon 2470, requires twice the number of pins to outperform the fastest split pin systems, such as the Omnigrid line of microarray printers manufactured by Genomic Solutions. Throughput may or may not be an issue, but when dealing with proteins, most researchers need the process to take as little time as possible.

## GENOME–PROTEOME CONTENT CURRENTLY USED FOR BIOMARKER RESEARCH

There is a need for an expressible open reading frame (ORF) eome that can be made into an arrayable proteome in the search for disease biomarkers. The number of proteins that are available for screening limits disease biomarker discovery. For example, in the search for human autoantigens, the availability of proteins to use in screening studies has been a bottleneck. The National Institutes of Health (NIH) has a collection of approximately 29,636 human ORFs that contain 17,526 (source: http://mgc.nci.nih.gov/) nonredundant gene sequences. Although Invitrogen has cloned all the human ORFs into their Gateway system, the creation of an assayable human proteome has been limited by the protein purification process. After almost a decade, the number of human proteins contained on their commercial Human ProtoArray chip remains at 8000 (<30% coverage). Recent work has shown that that these ProtoArray human protein chips, although limited in scope, have been used successfully to identify serodiagnostic autoantigens (cancer biomarkers). Hudson et al. profiled serum samples from 30 cancer patients and 30 healthy persons using microarrays containing 5005 human proteins. Ninety-four discriminatory serodiagnostic antigens were identified that exhibited enhanced reactivity from sera in cancer patients relative to control sera [7]. This is a good proof-of-principle experiment that should be expanded to verify that the 30 serum samples used for this experiment are actually representative of the ovarian cancer population as a whole, not just markers for families that are predisposed to this type of cancer but may never develop the disease. An additional control would have included serum samples from the sisters of the patients who did not have ovarian cancer.

To assay even a small population with an appropriate number of controls is financially prohibitive using the commercially available human ProtoArray. The array is available for $3000 each. For this reason the Human ProtoArray

chip offered by Invitrogen has not been utilized for large-scale screening. Small-scale experiments may be fine for a publication, but to identify robust biomarkers there needs to be a massive screening that allows profiling as many healthy, predisposed, and diseased persons as possible so that the data derived from the experiment are biologically relevant. It is only at this scale that we can truly make any conclusions about the immune response. The reason that we still have not found the ideal biomarkers is due to the complexity of immune response and its variability from person to person. The current human protein chip is being distributed as a consumable with a sizable price tag. To attempt a study of the size required to determine disease-state discriminatory antigens, or groups thereof, there needs to be a higher-throughput, more cost-effective method of generating the human proteome chip.

Infectious disease biomarker discovery faces challenges as well. Purified proteins of many infectious agents are scarce. Purified protein microarrays of pathogens usually include only a handful of proteins. The lack of content has been the major reason for the slow rate of emergence of new serodiagnostic markers. For example, only 149 out of the 4198 ORFs (3.5%) constituting the *Yersinia pestis* proteome were used to profile the antibody response to live vaccine [8]. In addition, 156 out of approximately 1000 (15.6%) *Chlamydia trachomatis* proteins were used to profile the human humoral immune response to urogenital tract infections in human subjects [9]. The ability to express and purify recombinant proteins in the lab limits the amount of unique content available for serological screening. This low percentage of proteome coverage is common, and most laboratories in this field are studying a few antigens at a time from thousands of possible candidates.

One of the innovative ways is which researchers have overcome the lack of coverage is to apply the lessons learned from whole-cell Western blots and two-dimensional gels to microarray research. Native protein microarrays are heterogeneous protein pools that have been fractionated using chromatography. Sartain et al. developed a technique for the separation of native *Mycobacterium tuberculosis* cytosol and culture filtrate proteins that resulted in 960 unique protein fractions that were used to generate protein microarrays. These 960 fractions represented all the expressed proteins, having some proteins represented in different fractions. When these microarrays were used to profile the reactivity of different disease states, various previously characterized proteins as well as some novel proteins were identified from these fractions using mass spectrometry [10]. A similar approach was utilized in a different field to profile the sera of prostate cancer patients and controls. Two-dimensional liquid chromatography was used to separate proteins from the prostate cancer cell line LNCaP into 1760 fractions, which were subsequently spotted onto a microarray. The microarrays were probed with serum samples from 25 men with prostate cancer and 25 male controls. Statistical analysis revealed that 38 of the fractions showed significantly more reactivity in the cancer group. Samples were classified with up to 98% accuracy using the same sera [11]. Although a good academic exercise, the protein fraction microarray

needs further studies to uncover the proteins responsible for the reactivity. In the tuberculosis case, mass spectrometry was able to characterize a number of reactive proteins, but the authors conceded that this approach was a stopgap until the complete proteome is cloned, expressed, and arrayed. In the case of prostate cancer the reactive fractions must be analyzed further to determine which of the many proteins represented in the fractions are the important ones. Another challenge that faces users of protein fraction microarrays is that proteins are not all represented equally in these fractions. Antigens that potentially are extremely good biomarkers may be underrepresented, due to an expression level regulated by cell degradation pathways that may target these proteins.

## HIGH-THROUGHPUT GENE CLONING AND EXPRESSION FOR THE FABRICATION OF PROTEOME MICROARRAYS

The genomics era ushered in a new type of research. For the first time in history the decoded "blueprint of life" was available for study. The Human Genome Project (HGP) was the first major undertaking of its kind. The HGP was a 13-year project coordinated by the U.S. Department of Energy and the National Institutes of Health that was completed in 2003. The goal was to identify all of the approximately 20,000 to 30,000 genes in human DNA, determine the sequences of the 3 billion chemical base pairs that make up human DNA, and store this information in databases. This initiative sparked the boom in genome sequencing, and today there is a vast amount of publicly available data stored in numerous databases. The genomes of more than 180 organisms have been sequenced since 1995, and the data from these projects are available to the scientific community. The availability of genome sequence data leads to the first big boom in microarray research. Researchers used this sequence to create libraries of oligo nucleotides representing all the ORFs of the organism being studied. Robotic machines were then used to transfer and arrange nanoliter amounts of thousands of gene sequences representing a cell expression state on a single microscope slide. These high-density, highly organized arrays of DNA are called *microarrays*. DNA microarrays allowed for the miniaturization and high-level multiplexing of Southern blots. Affymetrix and Agilent technologies pioneered the use of DNA microarrays for full genome gene expression analysis. Researchers were now able to track the expression of genes in response to various stimuli and incorporated this new tool in their existing research. They could track the synthesis and degradation at the mRNA level, to determine which genes are turned on and which are turned off in a given cell. We now knew the number and sequence of the expressible genes and the expression pattern of the genes in response to a particular stimulus. An area that still needs to be explored, however, is how the proteins performing their function once expressed. This conundrum has ushered in the age of protein microarrays.

Currently, protein microarrays are being used for a variety of assays. There has been much trial and error when attempting to miniaturize binding assays, enzyme activity assays, and serological assays. The same tools that helped propel the era of the DNA microarray are being applied to protein microarrays. Protein microarrays permit the miniaturization and high-level multiplexing of protein-based assays. Companies like Protometrix cloned, expressed, and purified thousands of proteins to make the Yeast Proteome chip and the Human Partial Proteome chip. The Human chip, now on version 8, is available commercially from Invitrogen, with approximately 8000 human proteins that can be used for screening binding partners, substrates for enzymes, small molecules, and antibody profiling. That is the equivalent of 8000 co-sedimentation assays, 8000 phosphorylation assays, or 8000 ELISA assays on a surface area of 3 inches × 1 inch. When all the approximately 29,000 ORFs that have been cloned are eventually expressed and printed on a microarray, all proteins expressed by human cells will be contained on two or three microscope slides and ready for assay.

Traditional multistep cloning methods have been a major stumbling block because of their innate low throughput. Starting first by amplifying the desired insert by polymerase chain reaction (PCR), then digesting it and the vector, followed by ligation, subsequent transformation, plating, colony picking, and verification of clones, the volume of work is the rate-limiting step. Technical problems may be encountered in any of the aforementioned steps, and most often than not, researchers spend months cloning a few genes of interest. There are, however, ways to circumvent this laborious cloning methodology when attempting to manufacture a high-content microarray.

One way is to take advantage of the vast genomic sequence data and the high-throughput friendly PCR reaction to amplify out all of the ORFs, followed by a second PCR step to make the products transcriptionally active. The secondary PCR step adds a promoter region at the 5′ end and a stop codon at the 3′ end of the PCR product, making a transcriptionally active PCR (TAP) product. The production of TAP fragments for expression can yield a large library of expressible ORFs in a relatively short amount of time. TAP fragments have been reported to express very well in a variety of expression systems [12]. Organisms with large genomes that would otherwise take decades to clone into an expressible form will now only take two rounds of PCR. A recent report by Regis et al. has shown that in the case of *Plasmodium falciparum*, TAP fragments could be used for a large-scale screening of the humoral immune response and eventual selection of antigens for further study [13]. While providing the throughput, TAP fragments are limited by the amount of product produced during the second PCR step.

Recent research has shown that serological screening of cDNA libraries created from cancer cell lines can be used for the discovery of cancer biomarkers. Cancer is the result of a synergistic malfunctioning of multiple signaling pathways. This may or may not be the same set of pathways, proteins, and mutations in every cancer type and tissue, so it becomes even more critical to

cast the widest net to find the most potential biomarkers [14]. Lung cancer cell lines were used to make cDNA libraries that have been used successfully for serological identification of serodominant antigens [16,17]. This is encouraging, but the task at hand with this technology is more daunting. After the creation of the reverse complement of the mRNA, there is still a need to use brute-force cloning techniques to accomplish the task. One must keep in mind that the majority of mRNAs in most tissues are in low abundance, and thus quite a few of the mRNAs will be underrepresented in the cDNA library [15,18]. Extremely large number of clones are required to ensure a good representation of these low-abundance genes. There is also the very real problem of partial cDNA clones, which do not have the complete sequence. If we are fortunate enough to minimize these two issues, there is still the very real bottleneck of screening the clones. High-density gridding is becoming more and more common and makes it possible to screen large amounts of mRNA complementary DNA. This technology is designed largely for gene discovery, but if refined to the point that all mRNA transcripts are represented equally, we may have a tool for more reliable screening of human serum samples.

The next rung on the ladder would be the creation of an expressible genome library that contains all the ORFs in the genome. To make the genome library quickly and efficiently, we need to consolidate all the traditional cloning steps into one efficient step. Recombination in vivo provides the all-encompassing single step. Recombination cloning is widely used in research, but for a long time it was thought that bacteria lacked the mechanism to allow for recombination. However, bacterial in vivo homologous recombination has been an efficient and heavily used tool in the genetic field. Recombination-based cloning allows DNA sequences to be inserted or deleted without regard to location of restriction sites [19,20]. One very widely used methodology for recombination cloning is the Gateway system now offered commercially by Invitrogen. The first step to Gateway cloning is inserting the gene of interest into the Gateway entry vector. There are two ways to clone your gene of interest into a gateway entry clone. The first is the standard cut-and-paste protocol using restriction enzymes and ligase. The second way is to create a PCR product with terminal attB sites, using primers containing a 25-base pair attB sequence, plus four terminal G's. This product will then be inserted in the entry clone using reconstituted recombination machinery. PCR-based inserts can be made using genomic DNA, a cDNA library, or an plasmid clone containing your gene of interest. An entry clone is a vector containing your gene of interest and flanked by Gateway *att* recombination sites. Bacteriophage lambda *att* site recombination is a well-characterized phenomenon [21]. Bacteria have a stretch of DNA sequence called *att* encoded into their genome, and bacteria phage have the same stretch of DNA sequence. When the phage infects a bacterium, the lambda DNA injected recombines with the corresponding bacterial DNA via the *att* sites in the presence of integration-specific enzymes. The enzyme-assisted recombination results in integration of the phage DNA into the bacterial genome. Using the same reconstituted lambda

*att* site recombination system, entry clones containing a gene of interest can then be transferred into any expression vector for subsequent protein expression. Although the Gateway System works and increases cloning throughput dramatically, it is not efficient enough to work as a true high-throughput alternative.

In vivo recombination cloning directly into an optimized expressible vector, however, appears to have solved the throughput dilemma. Recent advances in cloning methodologies have resulted in the ability to clone entire bacterial ORFeomes, comprising thousands of genes, in a relatively short time. Figure 2 illustrates the typical results one would see beginning with the PCR step followed by the in vivo recombination cloning, and checking the clones by PCR using sequence specific primers. Specifically, in vivo recombination cloning [22] in *Erscherichia coli* has broken the barriers posed by traditional brute-force cloning methodologies that rely on multiple-step cloning techniques: from PCR, restriction enzyme digestion of the PCR product and vector, ligation, to single colony screen and selection. Available sequence data are used to design 5′ and 3′ gene-specific primers for all ORFs encoded in the genome. The primers contain 53 nucleotides, which are comprised of a 33-nucleotide recombination adapter sequence and a 20-nucleotidegene specific sequence. The PCR products are then mixed with a T7-based linear expression vector as described previously [22] and transformed into supercompetent DH5a cells (Antigen Discovery Inc.). The cells transformed are grown overnight and are checked for turbidity the following day. DNA can then be purified from the mixed cultures using 96-well plate–based mini-prep protocols such as Qiaprep Turbo 96.

The plasmid DNA purified from overnight culture can then be used to express the protein encoded by the insert. Proteins are expressed in a coupled in vitro transcription-translation (IVT) reaction in an *E. coli*–based cell-free

**Figure 2** Synthesis and verification of clones. Representative images of whole Vv ORFeome PCR (A), cloning (B), and QC-PCR (C).

expression system such as RTS 100 from Roche. The unpurified proteins can then be printed directly to nitrocellulose-coated slides along with a set of negative and positive controls using a contact microarray printer. It is crucial that the mixture of unpurified proteins be spotted as quickly as possible. The quality of the arrays is inversely proportional to the amount of time from the end of the reaction to the deposition onto the nitrocellulose. Once the unpurified protein mixture is spotted and dry, it is very stable.

In the high-throughput microarray fabrication first reported by Davies et al. in 2005 [22], the cell-free expressed proteins can be detected using antibodies against the N-terminal polypolyhistidine (polyHis) tag and the C-terminal hemagglutinin (HA) tag directly on the chip. The antibodies were used to monitor expression of the large numbers of parallel reactions. The arrays probed using a mouse monoclonal antibody raised against the polyHis epitope and rat monoclonal antibody raised against the HA epitope are visualized using a fluorescent-based microarray scanner. An example of one such hybridization and scanning output can be seen in Figure 3. The data can then be quantified using a microarray data analysis software package that can quantify the intensity of the spots on the microarray chip. Each array contains positive control spots printed from serial dilutions of whole immunoglobulin G (IgG). Each array also contains no DNA negative control spots, and the reactivity of

(A) (B)

**Figure 3** Quality assessment for protein expression. Images of whole Vv proteome microarray probed with mAb against polyhistidine (A) and hemoagglutinin tags (B). 99.0% of Vv proteins were reactive to antipolyhistidine antibody and 88.2% to anti-hemoagglutinin antibody. The images show four dilutions of human IgG (yellow box), positive controls (green box), and six negative controls (mock transcription/translation reaction) (red circles). The remaining spots are Vv proteins. (*See insert for color reproduction of the figure.*)

these spots is low for both serum samples. The positive and negative controls are used to normalize the data using a modified VSN package in a statistical environment named R [23,24] from arrays that are probed on different days. There are also serially diluted EBNA1 protein control spots, which have been shown to be reactive to varying degrees in different human subjects [25–27]. Once an array has passed quality assurance, it is ready to be used in serological studies.

## USING WHOLE PROTEOME MICROARRAYS TO SCREEN FOR DISEASE-STATE DISCRIMINATORY ANTIGENS

The ability to find biomarkers relies on the ability to profile the immune response to entire proteomes. Antigens that are highly reactive to infection, or auto-antibodies, can be used in diagnostics and therapeutics. They are also potential candidates for the development of vaccines.

Using the model organism vaccinia virus Western Reserve strain, researchers were able to use in vivo recombination cloning to clone the 185Vv proteins, or greater than 90% of the proteome, from genomic DNA into an expressible vector. This proteome vector library was subsequently expressed and arrayed onto nitrocellulose-coated slides. Each slide contains 16 nitrocellulose pads with a Vv proteome array per pad. Each slide is capable of producing serological data for 16 serum samples interrogating approximately 200 spots (185Vv proteins plus controls), yielding 3200 data points per slide, the equivalent of thirty-three 96-well ELISA plates. Davies et al. [22] showed that there are specific vaccination-state and disease-state profiles that are discernible using whole proteome screening. Comparing the pre- and postvaccination data for each species, naive mice, monkeys, and humans have a very different reactivity pattern than that of vaccinated mice, monkey, and humans. In Figure 4 we see one such example comparing the hyperimmune serum vaccinia immunoglobulin (panel A) from Cangene and a naive subject (panel B). These results verified that this platform was a rapid way to scan humoral immunity comprehensively from vaccinated or infected humans and animals on a whole proteome scale [22]. In 2008, Davies et al. showed the power of the technology for profiling the immune response. Figure 5 is a heat map of an experiment comparing the immune response of two different stains of vaccinia virus. The U.S. government is considering using modified vaccinia virus Ankara (MVA) as a smallpox vaccine to replace live vaccinia virus, otherwise known as Dryvax, because it is safer. The heat map is a global view that allows for comparison of the immune response elicited by MVA and Dryvax and can give us an idea of whether it elicits a similar response to confer protection.

Barbour et al. recently published an article that takes advantage of this technology to clone and express 1292 *Borrelia burgdorferi* proteins. Employing enzymeless recombination cloning and *E. coli* cell-free expression, they produced a protein array representing approximately 80% of the genome. The

(A) (B)

**Figure 4** Naive subject serum and VIG. Images of whole vaccinia virus proteome microarray probed with vaccinia immunoglobulin (Cangene) (A) and naive individual (B). The IgG control spots (shown in yellow) show signal intensities for both samples; both objects do not react with the no-DNA control spots (shown in red). The images show four dilutions of human IgG (yellow box), positive controls (green box), and six negative controls (mock transcription/translation reaction) (red circles). The remaining spots are Vv proteins. (*See insert for color reproduction of the figure.*)

antibody reactivities of sera from patients' Lyme disease were compared to the antibody reactivities of sera from controls. Overall, approximately 15% of the (ORFs) of *B. burgdorferi* in the array elicited an antibody response in humans with natural infections. Among the immunogens, 103 stood out on the basis of statistical criteria [26].

In 2007 this same platform technology allowed fabrication of the *Francisella tularensis* proteome. The proteome was interrogated with serum samples to find biomarkers that are specific to tularemia, the disease caused by *F. tularensis*. This particular study was looking at the efficacy of subunit vaccines, and the proteome arrays were used to take a look at the humoral response to different vaccination protocols. The stimulation of a protective immune response against intracellular pathogens using nonreplicating vaccines was investigated. Many of today's vaccines still use attenuated organism vaccines or a different less virulent strain as a vaccine. Eyles et al. showed the effect of different adjuvants on the response to the nonreplicating vaccine. The *F. tularensis* proteome chips were used to effectively differentiate which adjuvant was stimulating an IgG1 or IgG2 response. An IgG1 response is related to the TH2 receptor and does not confer protection. An IgG2 response is associated with the TH1 receptors and has been shown to be associated with protective immunity. Furthermore, these data give insight into the protective immune response

**Figure 5** Antibody profiling of human antibody profiles for pre- and postvaccination with MVA (A) and WR (B). For Dryvax responses, primary ($n$ = 13) and secondary ($n$ = 12) infections are shown. (From ref. 25.) (*See insert for color reproduction of the figure.*)

and have potentially important implications for the rational design of nonliving vaccines for tularemia and other intracellular pathogens.

Recent developments in the fabrication of protein microarrays allow the multiplexing of the entire proteome in profiling the immune response. This approach is powerful enough to discover content to finally replace tests used currently to diagnose infectious disease, some of which were developed over a century ago. The diagnosis of tuberculosis (TB) is an excellent example of such an opportunity. TB is a major cause of illness and death worldwide. Globally, 9.2 million new cases and 1.7 million deaths from TB occurred in 2006 [28]. Multiple tests must be performed to diagnose TB. A person sus-

pected of having TB is first tested using the tuberculin skin test (TST), also known as the purified protein derivative (PPD) test, pioneered by French physician Charles Mantoux in 1907. The TST is used routinely in humans, but the results are subjective, variable, and their interpretation is rarely consistent [29]. Sputum testing identifies *M. tuberculosis* directly, providing specificity, but current methodologies do not give good sensitivity [30,31]. The gold standard for the diagnosis of TB is a bacterial culture, which is a time-consuming process that requires a dedicated microbiology lab and several weeks to obtain the results [32]. More novel and sophisticated methods such as real-time PCR (RT-PCR) and cell-mediated-immunity–based detection assays, such as interferon gamma release assays (IGRAs), are accurate but require sophisticated equipment and highly trained personnel [33,34]. The limitations of the current TB diagnosis techniques have sparked renewed interest in antibody detection–based tests, which are relatively straightforward. The immune response to TB infection is variable enough that an infected population may not recognize a single antigen [35–40]. Methodology using previously characterized *M. tuberculosis* proteins using immunoassays such as ELISAs and microbead suspension assays for the purpose of TB diagnosis have shown the need of a multiplex approach at diagnosing TB [41,42]. There is a dire need for the discovery of an optimal panel of antigens that will allow accurate and reliable diagnosis.

Cancer is another field that is in urgent need of diagnostics with improved accuracy. We have known that cancer cells produce auto-antibodies since the 1950s [43]. Researchers found that these auto-antibodies were against proteins that were associated with these cells. Auto-antibodies against the tumor suppressor p53 have been found in breast cancer, lung cancer, and ovarian cancer [44–47]. Proteins that are overexpressed in a cancer cells also elicit the production of auto-antibodies. For example, the overexpression of c-Myc is linked to the presence of auto-antibodies against c-Myc in lung cancer [48]. There is evidence that the immune system begins to produce auto-antibodies against cancer cell–associated proteins years, perhaps even decades, before the onset of disease [49–51].

There is a dire need for earlier and more accurate cancer detection. The development of "early warning" tests will ensure a better prognosis for the patient. Serological biomarkers can also be a tool for the development of antibody-based therapeutics to treat cancer. To achieve this objective, it is important to identify sets of cancer-specific antigens, or biomarkers, that can differentiate disease states as well as different forms of cancer. Serum auto-antibody profiling is a promising approach for early detection and diagnosis of breast cancer. It is becoming more and more clear that it will take more than one marker to achieve the early warning system that cancer clinicians so desperately seek, and it is likely that well-characterized panels of biomarkers will be required. Zong et al. recently tested a breast cancer T7 phage library with healthy control sera and breast cancer sera and concluded that a panel of auto-antibodies, not a single auto-antibody, is required for optimal accuracy of disease-state discrimination [49]. A similar study tested colon cancer sera

with a colon cancer T7 phage library. Ran et al. were able to identify 24 autoantigens associated with colon cancer. A six-marker (six antigens) achieved 91.7% sensitivity and 91.7% specificity in the training set of sera. In a testing set with this marker panel, they predicted 85% of the samples correctly [52].

There are approximately 30,000 ORFs in the NIH human gene collection, representing 17,500 nonredundant genes and variants there of [53]. Using enzymeless recombination cloning, a human proteome chip could be made with upward of 90% of the ORFs represented. With the ability to assay 27,000 proteins at once, the discovery of new biomarkers for human disease will be limited only by the number of serum samples used to determine disease-state discriminatory sets of antigens, and potentially, antigen panels that differentiate between manifestations of the same disease, such as cancer.

## SUMMARY

The high-throughput proteomics approach described here is the natural progression of the genome sequencing projects of the 1990s, but instead of sequencing the genome, we are fabricating the proteomes. Organisms such as *M. tuberculosis* with 4000 ORFs, or malaria (*P. falciparum* and *P. vivax*) with even larger genomes, can now be assayed on a whole-proteome scale. By providing a comprehensive tool to test all the proteins at once, we open the door to a new nonbiased approach in biomarker discovery. Instead of working with a handful of proteins and attaining very limited data sets, we can now look at these organisms from a whole-proteome perspective, allowing the immune system to tell us what is and is not important. Although this approach has been used primarily for infectious disease research, it also holds promise for the discovery and study of biomarkers for human disease.

# CHARACTERIZATION AND VALIDATION BIOMARKERS IN DRUG DEVELOPMENT: REGULATORY PERSPECTIVE

Federico Goodsaid, Ph.D.
*Center for Drug Evaluation and Research, U.S. Food and Drug Administration, Silver Spring, Maryland*

## INTRODUCTION

Biomarkers can be considered tools to be qualified in close association with individual submissions for drug approvals. The U.S. Food and Drug Administration (FDA) Drug-Diagnostic Co-development Concept Paper [1] described a specific example of this association, where the approval of a drug and a test are closely linked with each other in both their product concepts and the timelines of their regulatory approvals. Several examples of biomarkers approved through this co-development process are shown in the FDA's Table of Valid Genomic Biomarkers in the Context of Approved Drug Labels [2]. Biomarkers in this table include both genetic and translational entries. Genetic biomarkers are often integrated in drug development as clinical or nonclinical markers of drug efficacy or safety for the purpose of patient selection in clinical trials, response prediction through stratification or enrichment, or dose optimization. Translational biomarkers have applications similar to those of genetic biomarkers but may also be useful for response monitoring and as early indicators of toxicity or adverse reactions.

Novel approaches are being tested continuously for the successful integration of biomarkers in drug development. Their applications range from early compound selection through postmarketing applications. However, integration of these novel biomarkers into routine nonclinical and clinical practice, and regulatory submissions, have often been slow. Hesitation in the application of these tests is often associated with fear not only about how comprehensive data supporting these applications are but also about the regulatory interpretation of the context of use for these applications [3]. Biomarker tests can be integrated into drug development when we have a consensus about the context in which we are measuring the biomarker and the evidence supporting this measurement. These levels of consensus need to be reflected in the regulatory review of biomarker data.

## REGULATORY PATHS IN BIOMARKER EVALUATION AND QUALIFICATION

The path from an exploratory biomarker to a biomarker qualified for a specific application context can be long and unpredictable [4]. Application of these biomarkers requires an objective record for their nonclinical or clinical context and supporting qualification evidence. Information from the development of exploratory biomarkers has been shared between the pharmaceutical industry and the FDA through voluntary exploratory data submissions (VXDSs) [5]. Submissions of exploratory biomarker data have allowed reviewers at the FDA to share with scientists in the pharmaceutical industry study designs, sample isolation and storage protocols, technology platforms, analysis algorithms, biological pathway interpretation, and electronic data submission formats. This experience has been valuable in training our reviewers for the analysis and interpretation of biomarker data.

VXDS have stressed the need for a regulatory path from exploratory biomarkers to biomarkers qualified for a specific context. Such a path is currently being tested at the FDA through a pilot process for biomarker qualification [6]. This process is focused on the specific needs of the regulatory environment to ensure scientifically accurate and clinically (or preclinically) useful decision making. In the first use of this new joint-agency review process put in place by U.S. and European drug regulators, the FDA and the European Medicines Association (EMEA) [7] allow drug companies to submit the results of seven new tests as evidence of nephrotoxicity by new drugs. At this time, the qualification of these biomarkers covers voluntary submission of these data for rat studies. On a case-by-case basis, the FDA will also consider possible application of these biomarkers in phase I human trials. The tests measure levels of seven key proteins or biomarkers that scientists from the FDA and EMEA believe provide important new safety information about the effect of drugs on the kidney. When reviewing investigational new drug (IND) applications, new drug applications (NDAs), or BLAs, both regulatory agencies will now

consider the test results in addition to blood urea nitrogen (BUN) and creatinine.

The development of the new renal toxicity biomarkers was led by the Predictive Safety Testing Consortium (PSTC) [8], whose members include scientists from 16 pharmaceutical companies. The PSTC was organized and led by the Critical Path Institute [9]. Researchers from Merck and Novartis identified the new biomarkers, tested them to prove their sensitivity, specificity, and positive and negative predictive value, and then shared their findings with the other consortium members for further study. The consortium then submitted applications for their qualification to FDA and EMEA.

This is a unique example of how a group of drug companies can work together to propose and generate qualification data for new safety tests and then present them jointly to the FDA and EMEA for qualification. The FDA and EMEA laid the groundwork for such joint-agency reviews in 2004 with the development of the VXDS framework. The VXDS review served as the baseline model around which to design the pilot process for biomarker qualification in 2006. A similar biomarker qualification data submission (BQDS) meeting is held in this pilot process to allow an exchange of questions with the sponsor about scientific and clinical information submitted for qualification.

The pilot process for biomarker qualification allowed the PSTC to submit a single application for biomarker qualification to both regulatory agencies, and then to meet jointly with scientists from both agencies to discuss it in detail and to address additional scientific questions posed by the regulators. Each regulatory agency reviewed the application separately and made independent decisions on whether each would allow the new biomarkers to be used. The new biomarkers qualified by FDA and EMEA are KIM-1, albumin, total protein, $\beta_2$-microglobulin, cystatin C, clusterin, and trefoil factor-3. Testing for these proteins will help scientists assess whether a drug is likely to cause damage to the kidneys, a toxic side effect of some drugs. At this time, both FDA and EMEA require drug companies to submit the results of two other tests, BUN and serum creatinine, to show whether such kidney damage has occurred.

The seven new tests may provide important advantages over these two tests. For example, in the rat model, once kidney damage has begun to occur, it takes a week before the two current tests can detect it [10]. The new tests are more sensitive and can reveal cellular damage within hours [11]. BUN and serum creatinine show that damage has occurred somewhere in the kidneys, but the new tests can also pinpoint which parts of the kidney have been affected [12]. Although additional studies are needed, the new biomarkers may one day allow promising drugs to advance into clinical trials that otherwise would have been abandoned, because currently there are no tests available to detect early-onset renal injury. The seven new tests were developed and will be carried out initially in rats, but they were selected because other

studies have shown that similar biomarkers are produced in human kidney cells [13]. Although initially the FDA and EMEA will consider only data from rat studies, the PSTC will begin work to qualify these biomarkers in human studies. If these studies are successful, the PSTC will present a new application seeking acceptance of the human biomarkers over the next two years.

The need for an accurate, comprehensive, and efficient process for biomarker qualification is closely linked with our ability to quickly integrate new biomarkers in drug development and regulatory review. The biomarker qualification pilot process at the FDA is testing the scientific, clinical, and regulatory components for a biomarker qualification process. Experience gained with this pilot process will be useful in the development of a formal regulatory process for biomarker qualification.

## EVIDENTIARY RECOMMENDATIONS

The most difficult part of this process will be to define incremental contexts of use and the corresponding evidence with which biomarkers may be qualified. We should not misrepresent the industry goal: qualified biomarkers capable of managing new drugs in the clinic with nonclinical or clinical findings of nephrotoxicity somewhere in their previous developmental stages. We also cannot misrepresent the goal as far as public health is concerned, which is to obtain better biomarkers of nephrotoxicity for routine clinical use as quickly as the data will allow. Intermediate qualification contexts and data need to be defined so that investment in biomarker qualification studies will be productive both for clinics and for the pharmaceutical industry. Initial studies proposed by consortia are unlikely to match a clear context for qualification for a full clinical application of biomarkers. What intermediate contexts for qualification can we define, and what study characteristics can we propose for qualification in these intermediate contexts of use? Several authors [14,15] have proposed evidentiary recommendations for biomarker qualification.

Unlike the incremental process for biomarker qualification embodied in the pilot process for biomarker qualification at the FDA [7], papers on evidentiary recommendations often propose all-or-nothing qualification contexts, where if the ultimate goal is a clinical qualification, no intermediate qualification contexts are expected to be defined or qualified. This approach is not only time consuming but is also not likely to encourage the investment needed to generate data for biomarker qualification. At each stage, whether the context of use for a biomarker is to be in vitro, in a nonclinical animal model, or in the clinic, a company or consortium proposing a qualification will probably seek a quick return on the qualification of a biomarker after data are available to qualify a biomarker in a specific context in drug development. An effective process for biomarker qualification should include incremental application

context steps, so that these incremental steps can quickly benefit the drug development process.

## HARMONIZATION

The application of biomarkers to drug discovery and development has the potential of improving the efficacy and speed of bringing more effective and safer new drugs to market. This requires that biomarkers which may be applicable to such uses be qualified for a specific application context. To achieve this, both the process of qualification and the evidentiary criteria and standards for qualification will need to be described and defined. The International Committee on Harmonization's (ICH) E16 [16] is a harmonization effort to define the context, structure, and format of the biomarker qualification submission. It is based on the previous experience by the FDA and EMEA regarding biomarker qualification. This harmonization effort does not address the evidentiary requirements for biomarker qualification.

The structure, format, and content of a submission of biomarker data for qualification depend on the context in which the biomarker is intended to be used. The first step in drafting a submission for qualification of a biomarker is to determine its context of use, preceding specific decisions on applicable structure and format. The context of use for a biomarker is (1) the general area of biomarker application, (2) the specific applications/implementations, and (3) the critical factors that define where a biomarker is to be used and how the information from measurement of this biomarker is to be integrated in drug development and regulatory review. To demonstrate the alignment between proposed context and data, the initial context proposal must be supported by data available at the initial application step or expected to be available throughout the data evaluation process in biomarker qualification. There is a convergent relationship between an initial qualification context and the data supporting it. The initial gap between proposed context and data may need to be filled throughout the qualification process. Initial context proposals, however, should project a significant improvement over currently available biomarkers and/or endpoints.

The context of a biomarker drives data requirements to demonstrate its qualification for the intended application. The structure of a submission document ensures that the context and data can be submitted in a package consistent for consortia submitting qualifications as well as for reviewers in regulatory agencies evaluating a qualification package. The structure of a qualification submission is independent of the context of this submission, but must also be flexible enough to deal with the specific requirements of each context. On the other hand, the format of data required to qualify a biomarker may vary significantly with the context in which it is to be used. It is therefore only possible

to harmonize general regulatory guidelines on data format for biomarker qualification submissions.

## SUMMARY

The qualification of novel biomarkers for drug development and regulatory review is made possible by the development and testing of regulatory mechanisms for biomarker qualification. The urgency for getting more and better biomarkers to improve new drug development is clear to the pharmaceutical industry and regulatory agencies. Harmonized processes for biomarker qualification are being actively developed through ICHs harmonization procedures.

# FIT-FOR-PURPOSE METHOD VALIDATION AND ASSAYS FOR BIOMARKER CHARACTERIZATION TO SUPPORT DRUG DEVELOPMENT

Jean W. Lee, Ph.D., Yuling Wu, Ph.D., and Jin Wang, M.S.
*Amgen, Inc., Thousand Oaks, California*

## INTRODUCTION

Novel biomarkers have been discovered from recent research in genomic and proteomic studies. Differences in gene expression and protein abundance or modification provide the basis for novel biomarkers to be tested further with in vitro and preclinical disease models. Interactions of putative biomarkers at interwoven pathways and the intervening drug actions are relevant to polygenic disorders associated with the complex interplay between genetics, epigenetics, and the environment. Activities of novel biomarker development have increased, especially in diabetes, cancer, rheumatoid arthritis, and cardiovascular disease. In addition to clinical biomarkers proven previously, putative biomarkers have been included in clinical trials of new, mechanistic-based drug candidates for exploratory, demonstrative, or characterization applications in the process of developing mechanism-specific biomarkers toward the ultimate goal of surrogacy (Pepe et al., 2001; Wagner, 2002a; Bjornsson, 2005; Wagner et al., 2007). For example, to the commonly employed measurement of blood glucose, hemoglobin A1c, and circulating insulin, novel

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

biomarkers could be included in diabetes trials, depending on the mechanism of action. For peroxisome proliferator–activated receptor gamma (PPARγ) agonists in type 2 diabetes, free fatty acid was linked to insulin resistance as mechanism-specific, and adiponectin was identified as a proximal biomarker correlated with insulin sensitivity (Berger and Wagner, 2002; Wagner 2002b), while glycosylated hemoglobin ($Hb_{a1c}$) was qualified as a surrogate marker (Krishnamurti and Steffes, 2001). Other mechanisms and the relevant biomarkers (in parentheses), such as lipid and bone metabolism (free fatty acids, leptin, osteocalcin), incretins (glucagon, GLP-1), and inflammation (cytokines, hsCRP, PAI -1, fibrinogen, adhesion molecules) are also involved in the complex disease of diabetes (Lee and Pratley, 2005; Chu et al., 2006; van Doorn et al., 2006; Haffner, 2007; Liu et al., 2007). In addition to circulating prostate-specific antigen (PSA), carcinoembryonic antigen (CEA), and other tumor markers, the mRNA of specific genes, various growth factors, and imaging are also used in clinical trials to monitor drug responses for cancer treatments (Sweep et al., 2003; Rubin, 2004; Quraishi et al., 2007; Yu and Veenstra, 2007; Khatami, 2007).

The use of novel biomarkers has become a prominent component of decision-making processes in drug development. They are used in the in vitro and preclinical models and early clinical phase for quick-hit and early-attrition decisions (Bloom and Dean, 2003; Bjornsson, 2005; Lee et al., 2005; FDA CDER, 2006). Characterization of a novel biomarker in the translational phase requires data collection to show preclinical sensitivity and specificity, and linkage to clinical outcomes in multiple clinical studies in humans (Wagner et al., 2007). The purposes at this phase are different from the exploratory or demonstrative phase. In exploratory and demonstrative studies, pharmacodynamic (PD) correlations are typically unknown, data are used mainly for internal decision making, and the output will generally not be subject to regulatory review. The extent of method validation can thus be limited to a few basic components to expedite the process and preserve resources without unduly affecting commercialization (Lee et al., 2006). In contrast, the purposes of characterization application are to provide pivotal data to establish linkage to clinical outcome and to monitor patient progress upon treatment (Figure 1). The data are often used for critical decisions (such as supporting dose selection and patient stratification, and demonstration of drug safety or efficacy), submitted to review by regulatory agencies, or used for postmarketing patient monitoring (Kummar et al., 2007; Stoch and Wagner, 2007). In addition, the same method used for characterization is likely to be used in the qualification phase toward surrogacy, confirmed over multiple drugs of similar mechanism, and used during surveillance studies. Therefore, biomarker characterization studies would require more intense rigor in assay method validation and in traceable and more detailed documentation than that of previous phases to meet the study objectives in a defined context of use.

A biomarker is useful if there are distinctions in concentrations in the disease state from that of a healthy status (or disease stabilization, in the case

**Figure 1** Path from putative to confirmed mechanism of a novel biomarker through the processes from discovery to surrogacy. The side boxes illustrate the relationship of the processes to drug development applications and the methods required.

of some oncology trials). The assay performance of the biomarker analytical method must be able to meet this goal of disease status distinction and estimation of the drug effect. Therefore, contrary to the general perception of many analytical laboratories, the required assay acceptance criteria do not depend solely on the deliverable method's accuracy and precision. Instead, consideration should be on the assay suitability for the intended applications based on three major factors: (1) intended use of the data during various stages of drug development, (2) nature of the assay methodology and the different types of data that it provides, and (3) biological variability of the biomarker that exists within and between populations. The first factor helps shape the assay tolerance or acceptance criteria for biomarkers.

A fit-for-purpose method validation approach at various phases of biomarker application has been described by Lee and colleagues (2006). In this chapter we focus on how the fit-for-purpose method validation and assay application during drug development clinical trials can contribute to biomarker characterization.

## GENERAL PROCESSES

Quantification of protein expression is important when considering the translation of a candidate protein biomarker. If there are changes in posttransla-

tional modification of the biomarker, it would be preferable to be able to quantify levels of both protein expression and posttranslational modification, utilizing technologies such as ligand-binding assays (LBA), enzymatic assays, liquid chromatography–mass spectrometry (LC-MS) in multiple-reaction mode (MRM-LC-MS), protein assay, and real-time polymerase chain reaction (RT-PCR) genomics. LBAs can be performed in high throughput at a relatively low cost per samples, which is most advantageous for application through phases of characterization and qualification development of a novel biomarker. Therefore, LBAs have been widely used for protein biomarker quantification and will be the typical method for discussion in this chapter.

The developmental processes of a novel biomarker and a new chemical drug entity are intertwined (Lee et al., 2003, 2007). Biomarker development may happen concurrently with the development of a single or multiple drug candidates, a refined new chemical or biological entity, or for extended indications and/or additional mechanisms. The progress of a potential biomarker does not always coincide with or parallel that of a new drug candidate development. To utilize and integrate information from development of drugs in therapeutic programs and the development of relevant putative biomarkers, a detailed work plan can be prepared for the novel biomarker and the study objectives identified in the corresponding study protocols of each drug candidate. Innovative companies often organize biomarker work groups to facilitate timely input and communication among therapeutic areas and supporting teams.

As depicted in Figure 2, novel target (BMKa) and/or proximal biomarkers (BMKb) of a specific mechanism can be used for multiple drug candidates to prove the mechanism of action by drug intervention during the exploratory and demonstration phases. If the circulatory biomarkers are reflecting their actions in the target cells/organs, measurements of blood levels of the target and/or proximal biomarkers can be included during clinical trials for further characterization purposes. In addition, distal biomarkers (BMKi,j) of a specific disease indication that have been used for other drug compounds can be applied for a new drug of a different mechanism toward the same indication. In general, distal biomarkers are closer to the disease symptom magnification for efficacy and off-target indirect effects, while the target and proximal biomarkers are closer to the direct exposure effect. Thus, the establishment of PD relationships to pharmacokinetics (PK) is usually simpler for the target or proximal biomarkers, while linkage to a clinical outcome may be shown more readily by distal biomarkers. PK-PD modeling is used to correlate the dose–exposure effects. PK-PD modeling based on various mechanisms of action, direct and indirect drug effects, and reactions of biological cascades has been developed (Mager et al., 2003). For proof of biology, the biochemical coverage of biomarkers from target hit to distal to clinical outcome would provide a thorough understanding of drug effect and characterization of a novel biomarker, whether it is a target, proximal, or distal. Additionally, off-target negative effects should be monitored carefully by toxicity biomarkers (BMKt). Such information is vital in the selection of lead candidates and appropriate dose ranges for clinical trials (FDA, 2004).

**Figure 2** On- and off-target biomarkers of a specific mechanism of drug intervention. Possible relationship of biomarkers from a specific pathway to disease outcome. Other pathways may have common distal biomarkers that may be used as predictive index of the same disease outcome.

The application of a novel biomarker in clinical trials for the purpose of biomarker characterization is often included as a secondary objective in a clinical protocol, while toxicity and commonly recognized efficacy biomarkers may be included in the primary objectives. Characterization of a specific novel biomarker may be carried out on different new chemical entity development programs over several therapeutic areas. Therefore, it is important for the assay laboratory to have both a "big picture" perspective on the development of a certain novel biomarker and the specific purpose of the application of that biomarker in a clinical trial. The time required for biomarker assay development and method validation, the operational and logistical issues, including preanalytical factors, and the limitations in data interpretation are key elements for careful planning and execution to support biomarker development and its applications.

## METHOD VALIDATION AND ASSAY APPLICATION IN DRUG DEVELOPMENT

### Population Range and Assay Range

In the process of biomarker assay development and validation, samples from the target populations of healthy persons and patients are used to establish expected ranges and biological variations for a given biomarker. Knowledge

of these ranges and assay performance in these matrices are necessary for a number of reasons. The initial concentration ranges of healthy populations are usually available from literature or vendor brochures for previously identified biomarkers. During the characterization phase the range-finding experiments should include sufficient samples from individuals of the target populations (and extended populations if applicable) to enrich the existing information. Biological variation exists in some biomarkers. It is important to note the variable levels over time (i.e., diurnal, seasonal, and food effects) to plan the correct conditions and time of sample collection appropriately. In addition, biological variation can come from the changes in the binding-protein components in the biological matrices, affecting the biomarker measurement in some patient samples. The effect of matrix from patient samples is discussed further later in the chapter.

The results of the range-finding studies and the expected drug effect on the biomarker are used in the design of method validation and assay application in clinical studies. Knowledge of variation and modulation will power the sample size necessary to confidently detect relevant changes in a biomarker after therapeutic intervention. It is desirable to have the biomarker assay range cover the range of the target populations and the expected drug effect. However, this is often not possible. For example, most protein biomarkers are analyzed by LBA, with the assay working range dependent on the antibody reagents used, which is often different from the biological range. Additionally, the biomarker levels of one disease are often different from that of another. For example, inflammatory biomarkers such as IL-6 and TNFα in serum samples for healthy and rheumatoid arthritis patients are in pg/mL range, whereas those of sepsis patients are in the ng/mL range. Use of the inflammatory biomarkers for sepsis will require dilutions into the working range. Thus, application of these biomarkers to sepsis studies would require dilutional linearity during method validation, and the variability introduced by dilution should be monitored during in-study assays.

## Sample Integrity: Sample Collection at the Clinic

Sample integrity means that the measurement of a biomarker after collection, transport, and storage should yield a result as close to that which could be measured in as fresh a sample as possible. Sample characteristics can vary over time, in the fed state, or by age- and gender-specific factors, and by the methods used to prepare the sample. Sample handling can alter a sample irrevocably, so care must be used in specimen collection. Delays in specimen processing, addition of anticoagulants and other additives, type of collection vessel and storage tube, and a myriad of other preanalytical circumstances can affect a biomarker. A careful review of potential confounding variables is essential prior to method validation. Preanalytical variables have been shown to compromise data utility in proteomic biomarker discovery and validation (Ferguson et al., 2007; Banks, 2008).

Serum, plasma, or urine samples are the most common matrices during the characterization phase. For diseases involving the brain or central nervous system, cerebral spinal fluids are commonly used. Accessible cells from sputum, bronchial lavage, and blood cells are used for receptor functional measurements. The preservation of samples must be explicitly defined in the study protocol. Control and standardization of sample collection are especially necessary to minimize variability from multiple clinical sites. For both tissue collection and ex vivo stimulation assays, it is best to validate sample collection procedures using conditions that closely mimic the planned sampling protocol and to examine sample stability as soon as possible. If sample handling is complicated, it would be prudent to establish tolerance boundaries surrounding sample collection and processing for the clinical sites to abide and document. In addition, staff training and oversight procedures are essential for the monitoring and maintenance of sample integrity.

In some biomarker studies, normalization is used to correct concentration variability. For example, urine creatinine concentration is used to normalize hydration variability in urine samples. In that case, the assay of the normalizing factor should also be validated on stability and reliability prior to the clinical study.

During biomarker characterization, multiple clinical studies from multiple drug candidate development programs may be involved. It is important for the biomarker team to coordinate the study protocols to include standardized procedures for sample collection, shipping, and analysis and for sample storage and disposal. Sample collection and storage stability should be tested by the bioanalytical laboratory to cover the conceivable conditions during in-life study sample analysis. This includes process stability, assessing the impact of short- and long-term storage, and multiple freeze–thaw cycles.

## Method Development

***What Will Be Measured*** Many biomarkers of interest are proteins whose function is affected by a change in disease progression and drug intervention. The ultimate goal of a biomarker assay is typically to evaluate the effect on the biomarker activity in vivo, and a method that measures this activity accurately is most desirable. Direct measurement of changes to target cells, tissues, or organs in response to a drug is rarely feasible, and given current drug potencies, activity assays rarely have adequate sensitivity and precision. Moreover, cell-based and activity assays are usually laborious, low in throughput, and often lack definitive reference standards. LBA are often chosen for biomarker analysis over activity measurements because of their sensitivity, versatility in application, relatively high throughput, and low cost.

Many biomarkers are endogenous protein that can be physicochemically heterogeneous, with multiple forms present simultaneously. The concentration and biological activity of each component are often unknown and may vary with health status, over time, and between individuals. However, it is

desirable to know, even in the case of a well-defined regulatory peptide, the related species of the analyte existing in the biological matrix of measurement. For example, measurements of proinsulin, insulin, and C-peptide provide different information for clinical interpretation and assessment. For large molecules, the heterogeneity of the molecules poses challenges to identification of the exact species being measured. Therefore, various approaches in designing the analytical method, including choices of the reference standard and critical reagents, are worth considering.

LBA methods measure the binding reaction of the mixed components in the matrix. The majority of the data generated by LBA is relative quantification (Lee et al., 2006). Limitations of LBA methods are usually a lack of chemical information or correlation of the binding activity to the biological activity. In addition, the reference standard used for data regression may be a recombinant protein or one of several components which may or may not be representative of the entire endogenous mixture. However, as the purpose during biomarker characterization is to monitor population and longitudinal effects of drug treatment and disease progression, this type of relative quantification is adequately "fit for use."

***Reference Standard and Alternative Matrix for Standard Preparation*** The reference material may not be fully representative of the endogenous analyte because the endogenous analyte may exist in various forms in the biological matrix. A well-defined reference standard is used as a scalar for the relative measurement of the endogenous species. For example, the recombinant form of a biomarker can be produced and characterized with defined molecular size and purity to enable concentration and molar equivalence calculations. Documentation of the reference material is necessary for its use.

Most biomarkers are endogenous molecules with variable measurable amounts in the matrix. It is difficult to find "blank" control matrix for preparation of reference standards. An initial standard curve can be constructed by spiking the reference standard into a protein buffer solution. An initial screen on multiple matrix lots against the buffer standard curve may identify some blank matrix lots for standard preparation. When that is not possible, an alternative matrix can be prepared by depleting the endogenous analyte using methods such as charcoal stripping, high-temperature incubation, acid or alkaline hydrolysis, or affinity chromatography. Commonly, a protein-containing buffer or the matrix from another species with a non-cross-reactive homolog is used. The use of alternative matrices require studies of matrix effects and parallelism during method development and validation to understand the impact that differences from patient samples will have on assay results.

Parallelism experiments are performed through serial dilutions of a high-concentration sample with the standard matrix. Multiple individual matrix lots (three or more) should be tested to demonstrate lot-to-lot consistency. There are several ways to assess data of parallelism (Lee et al., 2006). The concentra-

**Figure 3** Parallelism of three individual matrix lots. Each lot is represented by a separate symbol. The sample was diluted with the standard diluent at dilution factors of 1.5, 2.5, and 5. The concentrations of the diluted and undiluted samples observed were all within the standard curve assay range. The mean of the calculated concentrations (observed concentration times the dilution factor) of each lot was determined. The ratios of the individual calculated concentration over the mean of the lot were plotted against 1/dilution factor. The data showed that the ratios were all within the range 0.8 to 1.2, which was the defined acceptance criterion of the assay. Therefore, the parallelism test results were acceptable for the test lots.

tions of diluted and undiluted samples observed should all be within the standard curve range. An example is depicted in Figure 3: The mean of the concentrations calculated (concentration observed times the dilution factor) of each lot was determined. The ratios of the individual concentrations calculated over the mean of the lot were plot against 1/dilution factor. Parallelism was demonstrated for the test lots because the ratio was not affected by the variable amounts of standard matrix introduced by dilution. When parallelism is not possible due to the unavailability of samples with sufficiently high concentrations of analyte, dilutional linearity should be tested in a manner similar to parallelism, except that high-concentration spike samples are used in place of the endogenous samples.

The failure to demonstrate parallelism should be taken into consideration in data assessment and interpretation. For example, it may mean that the values obtained should be treated as quasiquantitative instead of as relative quantitative measurements (Lee et al., 2006). In addition, within-subject comparison on a longitudinal time sequence would be more useful than between subjects or populations, which affects the clinical study design. All of these considerations would be dependent on the a priori goals of the study.

***Selection of Critical Reagents in Ligand-Binding Assays*** For the development of a first-in-class drug compound that targets a novel biomarker, assay reagents will need to be developed for both the drug candidate and the target protein biomarker. In the case of a macromolecular drug, often an analog of the drug candidate may be used as the binding reagent(s). On the other hand,

reagents for most off-target biomarkers may be available from commercial sources. These reagents may be established assay kits [U.S. Food and Drug Administration (FDA) approved for diagnostic use] or kits for research use only.

For the purpose of characterization of the biomarker of interest, fit-for-purpose method validation should be conducted with sufficient rigor to provide reliable data from multiple clinical studies. This should include assay range finding, accuracy and precision, selectivity, specificity, stability, and robustness (reproducibility) during prestudy method validation. Additional data will be collected from in-study assay performance, change control method validation, and long-term storage stability. Except in the case of FDA-approved diagnostic kits, many of the assay performance parameters will have to be established by the bioanalytical laboratory. For FDA-approved kits, because the application will be for drug development instead of diagnosis, some of the assay performance parameters will need to be established. These often include selectivity against the target patient sample matrices and specificity against the drug compound(s). If the drug is expected to decrease the biomarker to a level lower than the lowest standard of the kit, the method may need to be modified to increase assay sensitivity.

Antibody pairs are typically chosen as capture and detection reagents. In general, the more selective antibody would be chosen as the capturing agent, especially if it is more readily available than the other member of the pair. A tertiary detector antibody can be used that is conjugated to a reporter enzyme such as horseradish peroxidase. Alternatively, a biotinylated detector antibody can be used together with a biotin-binding protein (e.g., antibiotin antibody or an avidin-type protein) conjugated to a reporter enzyme. The sensitivity of an assay can be increased by varying the number of reporter enzyme molecules on the detection reagents, or by using multivalent strategies to increase the effective signal from each analyte captured.

Some assays use receptors or their fragments as binding partners, most often in concert with a specific second antibody. This arrangement can improve selectivity for specific ligands (e.g., a cytokine activated from a latent precursor, or a particular subtype of ligand with distinct binding characteristics from its homologs). The binding selectivity of such reagents can offer added biological relevance to quantification, and can suggest results that might otherwise be obtained only via functional assays.

***Critical Reagents Characterization, Consistency, Stability, and Documentation*** Characterization of a novel biomarker often involves many clinical studies that last for several years. If the studies are to be conducted within the same company or from a joint program from different institutions, plans should be made to provide consistent supplies of the same reference material and assay reagents throughout the studies. If the materials are from in-house sources, sufficient production of the reference standard and primary reagents should be assured. In addition, multiple preparations of labeled

detector reagents should be assessed during method validation. If the materials are from commercial sources, negotiation with the vendor should take place to assure a consistent and sufficient supply of the same batch material, if possible. Often, multiple batches of materials (reference standards and critical reagents) should be tested during method validation. Documentation should be obtained for the stability of the respective lots over the time span of a clinical study. Documentation of chain of custody should be similar to that of a good laboratory practices (GLP) study. For late-phase studies using multiple clinical sites, the use of a central sample repository offers numerous advantages in controlling the process of specimen collection and labeling of multiple biomarker assays.

In-study sample control (SC) charts such as those shown in Figure 4 can be used for trend analysis of assay performance and stability. A big pool of endogenous sample at low, middle, and high concentrations of a biomarker were prepared during method validation and monitored throughout in-study.

**Figure 4** Use of sample controls for trend analysis on variability. Low, middle, and high sample controls of a biomarker were monitored in Levey Jennings control charts. There was a noticeable shift in trend in all the sample control levels after run 27. The average, upper and lower control limits of analytical runs up to run 27 (B) were compared to the overall parameters (A). (*See insert for color reproduction of the figure.*)

The Levey Jennings control charts showed a noticeable shift in trend at all the SC levels after run 27, indicating a systemic bias. The average, upper, and lower control limits of analytical runs up to 27 (right panels) were different from the overall values (left panels). This shift was traced to a change in commercial kit lot.

## Method Validation on Performance Parameters

The foremost assay performance parameters to be established for quantitative methods are precision and accuracy. In addition to these two parameters, sensitivity, selectivity, specificity, stability, and reproducibility should also be demonstrated. These parameters are established during prestudy method validation to demonstrate reliably that the method is fit for the purpose of biomarker characterization over multiple clinical studies. If more than one bioanalytical laboratory is used, each additional laboratory should also demonstrate its ability to perform by conducting a full or partial method validation.

***Accuracy and Precision*** Method performance is consistently better understood and validated through the appropriate use of control samples. To ensure data quality, assay performance is evaluated during method validation with validation samples (VSs) and monitored during sample analysis with quality control samples (QCs). VSs are used in method qualification or validation to define intra- and interrun accuracy and precision, providing data to demonstrate the robustness and suitability of the assay for its intended application. On the other hand, QCs are essential in determining run acceptability during specimen analysis. However, many laboratories have not made the distinction, using the term QC for both VS (for prestudy method validation) and QC (for in-study run acceptance).

For a well-defined biomarker assay, at least six accuracy-and-precision validation runs should be performed to provide statistical data to calculate these assay parameters (DeSilva et al., 2003; Lee et al., 2008). Each run should consist of standards prepared by spiking the reference standard into blank biological matrix or an alternative blank matrix. QC/VS at low, middle, and high concentrations should be prepared in the biological matrix or alternative matrix by spiking the reference standard. In addition, sample controls (SCs) should be prepared by pooling authentic samples at the low and high levels of the biomarker to reflect the performance of the endogenous biomarker in assay precision, stability, and reproducibility. At least two sets of QC/VS and SC should be run with the standards in each accuracy and precision experiment.

Accuracy and precision can be evaluated from the total error of VS data from the validation runs in a way similar to that of the macromolecular protein drug as analyte (DeSilva et al., 2003). However, given biological variability and other factors in biomarker research, more lenient acceptance criteria may

be used for biomarker PD than that for PK studies. Still, it should be recognized that accuracy and precision data of VS in buffer provide only a relative quantification, which may be quite different from measurements in the authentic matrix.

Concentrations of the endogenous SCs will be determined by multiple validation runs. The true values are then defined after sufficient data collection from pre- and in-study validation. For example, the mean of 30 runs and 2 standard deviations can be used to define the target concentration and acceptable range of the SCs. Because the reference material may not fully represent the endogenous biomarkers, the SCs should be used for stability tests (such as minimum tests of exposure to ambient temperature and freeze–thaw cycle). In addition, the SC can be used for in-study, long-term storage stability analysis and for assessment of lot-to-lot variability of key assay reagents.

Regression models are essential for data calculation from sigmoid curves like those in LBAs. The most commonly used four- or five-parameter logistic regression should be evaluated in conjunction with weighting factors during method development. Final decisions on which curve-fitting model to use should rest on which offers the best fit for all the standards in the precision profile. In some cases, a less than optimal fit will suffice to allow for greater assay sensitivity.

***Sensitivity*** To provide data for PK/PD studies, assay sensitivity is usually defined by the assay lower limit of quantification (LLOQ), which is the lowest concentration that has been demonstrated to be measurable with acceptable levels of bias and precision and total error (the sum of bias and precision). However, low-concentration clinical samples may fall below the LLOQ (i.e., the method lacks the required sensitivity). In some instances, the investigator may want to use values below the LLOQ but above the limit of detection (LOD), to obtain a numerical estimate of the changes while recognizing the high variability below the LLOQ region.

LOD is often used as the analytical "sensitivity" of the assay in a commercial diagnostic kit. A common practice of diagnostic kits to determine the LOD is the use of extrapolated concentrations from a response signal of +3 SD (or −3 SD for a competitive assay) of the mean background signal from 30 or more blank samples. The National Committee for Clinical Laboratory Standards (CLSI) has recommended an approach for determining LOD (National Committee for Clinical Laboratory Standards, 1999; Tholen et al., 2004). This statistically sound approach evaluates the limit of blank (LOB) as type I error and LOD as type II error from sufficient numbers of blank and low concentration samples with normally distributed analyte concentrations. One approach of calculation is described briefly as follows: LOB is estimated from the blank result at the 5th percentile position. LOD is calculated as

$$\mathrm{LOD} = \mathrm{LOB} + c\beta\ \mathrm{SDs}$$

SDs is the estimated standard deviation of the low-concentration sample measurement, and $c\beta$ is a correction factor for the population bias:

$$c\beta = \frac{1.645}{1 - 1/[4(N-K)]}$$

Here $N$ is the number of determinations and $K$ is the number of sample sets.

The LOD determined by this approach would avoid the inclusion of analytical false negative and false positive values. Due to assay conditions being variable, each bioanalytical laboratory should determine the LOD using the CLSI approach instead of using the LOD stated in a kit brochure. If the LOD is used as the lower limit for data inclusion instead of the LLOQ, the user should justify such a choice and be aware of the risk being taken with the higher variability at the LOD to LLOQ range, interpreting the data with caution.

***Selectivity and Matrix Effect*** Selectivity is the ability of the assay to discriminate the analyte unequivocally in the presence of components that may be expected to be present in the sample and alter assay results. Lack of selectivity can result in signal inhibition or enhancement. The results can appear as false or negative positives (an over or underestimation of the analyte concentration). In general, signal suppression from binding proteins occurs more often for LBAs than that of enhancement, resulting in a negative bias.

Interference in an assay is the product of concentration of the interfering substance times the cross-reactivity (or binding inhibition). However, the concentration–response relationship of LBA is nonlinear, and often the magnitude of cross-reactivity (or inhibition) is not evenly dispersed over the entire assay range. Thus, a standard curve prepared in a protein buffer solution has higher optical density (OD) responses than that in biological matrices, while the differences in responses are variable over the standard curve. Moreover, a standard curve prepared in biological matrices from one person would have different responses than that of other people. Therefore, the estimate of interference should not simply extrapolate across the entire assay range or be represented by an $IC_{50}$ value.

Matrix interference should be surveyed in samples from normal and diseased donors, especially in samples from the anticipated patient population. Spike recovery using samples from persons in the target population should be performed. A later selectivity evaluation of LBA involves a parallelism test of high-concentration endogenous samples from many people diluted at ≥4 dilution factors with the standard diluent.

***Specificity*** Specificity reflects the ability of an assay to distinguish between the analyte of interest and other structurally similar components of the sample. For LBAs a specificity test should include test of interference from components that may specifically affect the binding reaction. For example, inter-

ference from the drug compound may alter ligand interactions with the capture reagent. If the ligand reagent of an LBA is the target drug or its analog, the presence of the drug compound at certain concentrations can interfere with the assay. In addition, biomarker homologs or endogenous molecules of the same family may contribute to specificity problems. If reference material of the potential interferent is available, specificity can be tested using various amounts of the test material spiking into various levels of VSs (Lee and Ma, 2007).

Specificity for the biomarker in the presence of the drug under study should also be tested, using samples from endogenous pools (such as the SCs), with and without the addition of the drug compound at various concentrations spanning the expected therapeutic range. Figure 5 illustrates a specificity experiment of a target biomarker (A) and its proximal biomarker (B), each tested with three sample pools at pM levels against various nanomolar drug concentrations. As expected, the test drug inhibited the quantification of the target biomarker at concentrations greater than 2 nM. For the proximal

**Figure 5** Method validation specificity tests of a target biomarker (A) and a proximal biomarker (B) against a drug compound.

biomarker, the test drug did not affect the assay at all test concentrations, which exceeds the highest expected concentration of the drug in the serum. The results illustrated that the drug affected only its target protein.

***Stability*** In addition to sample integrity during collection, stability of protein biomarkers and assay reagents is required to show that the assay is not compromised by this preanalytical factor. Stability information is gathered during method validation on short-term storage and process stability, and is extended through in-study validation for long-term storage stability. Reagent storage stability is tested on reference material stock solutions and ligand-binding reagent stock solution if information from the supplier is lacking. Working solutions will be prepared from the stored stock solution and assay performance compared to those from that of a freshly reconstituted solution. Process stability is evaluated at different time durations and various conditions to mimic possible sample handling in the laboratory from the results of SCs subjected to stress from multiple freeze–thaw cycles and temperature exposures (e.g., four cycles and up to 16 to 72 hours to at 2 to 8 °C and ambient temperature).

Long-term storage stability of the SCs should be started during validation and continued to support the drug development program. The acceptance criteria of storage stability are according to those established during method validation, prior to conducting the experiment. For long-term stability evaluation, in addition to comparison against the initial concentration, trend analysis can be more useful than the acceptance criteria strictly applied. This is due to the challenges of a kit lot change, potentially shifting the mean value of the SCs, and a new preparation of the standard curve, introducing systemic bias to add an error component that is not caused by the storage conditions (similar to that illustrated in Figure 4).

## Assay Application

Before sample analysis begins, a written method standard operating procedure (SOP) must be in place. Often, a validation report should also be issued. Documentation of sample assay should follow the SOP in a GLP compliance manner (see the discussion later on regulatory issues), with traceable records. The data should be stored in a secure place for auditing.

***Standard Operating Procedure*** A validated method should have defined procedures, assay performance parameters collected from experiments using the same method during prestudy validation, and acceptance criteria established reflecting the acceptability of the method performance. These elements constitute a method SOP and are discussed in the following section.

*Method Procedures* A written method procedure should clearly describe the following:

- The intended purpose of the method
- The principle of the method
- A validation performance summary
- Materials and reagents, including lot numbers and expiration dates
- Solutions preparation
- Standards and QC, SC preparations
- Sample pretreatment (processing)
- Analytical steps
- Data regression
- Acceptance criteria
- References

During the development of a novel biomarker, a series of method modifications can take place. It is important that specific names (version number) and effective dates be given to the same method as that used in a clinical study. A historical log should be kept on the modifications made for each version, and its application in specific studies identified. Sometimes, for various reasons, if a method change has to happen within a clinical study, a crossover comparison of the old and new methods applied to a subset of clinical samples must be designed with a statistical approach to show method equivalence.

*Regression Model* The response–concentration relationship of the LBA method is nonlinear. Curve fitting would require regression model selection based on multiple runs of standard curves from the method validation accuracy and precision experiments. Typically, a four- or five-parameter logistic model will fit most methods with a choice of weighting factors (such as 1/response or 1/variance). The initial selection is based on the residual of the standard mean. It can be chosen to obtain the best fit over the entire range and with regard to the low end if sensitivity is an issue. The minimal total error of the VS data generated in the validation batches should be used to determine the regression algorithm and weighting. Once the regression model is chosen, it is a basic element of the method that should not be changed during assay implementation. Justification must be given and documented for a regression model change.

*Acceptance Criteria* Without sufficient data from the healthy and patient samples, the acceptance criteria for a novel biomarker can initially be set as determined by the assay performance from prestudy method validation. The biological data obtained from in-study validation from subject samples can then be used to refine the initial acceptance criteria set by the prestudy validation. The process of setting acceptance criteria for a protein biomarker measurement follows an evolving path. During the exploratory phase, the acceptance criteria were initially set according to the initial assay performance

of prestudy method validation. After use in pilot studies, assessment should be made on the suitability of the assay stringency vs. the effect observed. The biological data obtained from the in-study validation from subject samples during in-study phase can then be used to refine the initial acceptance criteria set by the prestudy validation. For example, an assay with 50% total error may still be acceptable for detecting a twofold treatment effect observed in the in-study phase clinical trial. Setting the same acceptance criteria of a given method may be most convenient for an analytical laboratory. However, for a novel biomarker, it may not be the most appropriate for all of its applications. One could take into account the intended purpose of the application and the possible outcomes in the analytical phase. For example, the effect of one population or indication may be different from another (e.g., change from a twofold treatment effect into only 30%), which may require a more stringent method and/or more subjects to increase the predictive power in such an application for the other population.

***Controls in Clinical Studies*** For a well-planned assay application, both analytical quality controls and biological sample controls should be available to assess the assay variability. Data of analytical variability are gathered from standards, QC and SC of each analytical run of sample analysis. A common set of SCs (or pools of incurred samples from a previous study) analyzed by multiple bioanalytical laboratories can provide an assessment of assay performance among the laboratories. Variability of supplies in reagents and reference standard materials can be detected by tracking the assay performance of a common set of SCs used within and between studies. An example is shown by an SC chart for serum C-terminal telopeptides of type I collagen (CTx) assay in Figure 6, using the Westgard rule for monitoring (Westgard, 2003) as well as a priori acceptance criteria of 25%. The low and high SCs were prepared by pooling a large volume of authentic samples, and the mean values were established during method validation. Figure 6 shows the Levey Jennings charts of more than 117 analytical runs from five clinical studies (A to F) over more than 2.5 years. During this time span, two reference stock materials and three kit batches were used. The plots show a slight positive bias in the SC values after the initial sequence of studies B and C. In addition, a slight negative bias was observed prior to study A. However, since the SC values were still acceptable within ±25%, no action was taken. Other statistical analysis can be use to assess SC data on other assay variability sources, such as operator differences and sample storage stability trend.

At the same time, data from predosed samples can furnish information on biological variability among the subjects and between studies. Figure 7 shows the baseline concentration distribution of TRACP 5b, a bone resorption biomarker, in various patient populations from four clinical studies. Statistical tools can be used to construct distribution charts of the predosed samples of each population, and cohorts can be compared. For pilot clinical trials with small number of cohorts, one should note that the data may not be normally

**Figure 6** Levey Jenning plots of low and high sample controls of serum CTx. Concentrations were plotted against run sequences labeled with the specified studies from A to F. UCL, upper confidence limit; LCL, lower confidence limit. Sample results exceeding the Westgard rule of 1:2 S (beyond 2 standard deviations) were marked.

distributed (example in Figure 7A and C) as compared to those with the late-phase clinical trials (example in Figure 7B and D). In addition, multiple collections of predose samples from the same subject can provide sample collection variables of multiple clinical sites.

***Confirming Selectivity in Patient Populations*** Biomarkers can reflect the dynamic changes in disease progression and response to therapy, but homeostatic and compensatory biological responses can alter the expected profile in response to drug treatment and concomitant therapies (Heeschen et al, 2003; Vural et al., 2006). In the latter case, biomarker assay selectivity is a critical component for interpreting biomarker responses and clinical data, particularly when a concomitant therapy is a potential interferent in the assay. For example, the bone turnover biomarker, serum CTx, is being used in clinical studies involving many different populations. During method validation, serum from healthy males and females and from patients with breast cancer, multiple myeloma, osteoporosis, and rheumatoid arthritis were analyzed with and without the addition of CTx at 0.145 ng/mL. The spike recovery was calculated

**Figure 7** Baseline concentration distribution of TRACP5b in various patient populations from four clinical studies: (A) patients with advanced cancer ($n$ = 105); (B) patients with prostate cancer ($n$ = 1427); (C) postmenopausal patients ($n$ = 222); (D) postmenopausal patients ($n$ = 7828). The curved line represents a fit by lognormal distribution. Outlier box plots are shown in the panels above the histograms. $X$-axis, concentrations of TRACP5b in ng/mL; $Y$-axis, relative frequency.

by subtracting the endogenous concentration of the unspiked sample from the spiked sample. The recovery data of the percent difference from the nominal value of the various populations were presented in Figure 8. The results show that all normal male and female serum recovered with the acceptance criteria (dashed line of ±25%). Recoveries were more variable with patient samples, although most of them were acceptable. The recovery data set of normal females had the best precision and was used as the control in Dunnett's method to compare with the other groups. The Figure 8 side bar shows that the circles of all groups were overlapping with the control group (bold circle). All groups had $p$-values less than an $\alpha$ of 0.05, while that of the rheumatoid arthritis group was 0.0587, possibly due to a slight interference from the rheumatoid factor in the samples.

*Specificity and Sensitivity of Novel Biomarker on Drug Effect* In-study data should be compiled and assessed to determine if (1) assay performances of

**Figure 8** Selectivity test of CTx in sera from healthy and patient populations. The populations included healthy male (normal M, $n = 20$) and female (normal F, $n = 20$); patients with breast cancer (BC, $n = 20$), multiple myeloma (MM, $n = 10$), osteoporosis (Osteo, $n = 18$) and rheumatoid arthritis (RA, $n = 10$). The normal male age range was 45 to 74, that of female was 38 to 67. Serum samples were analyzed without and with the addition of CTx at 0.145 ng/mL. The spike recovery was calculated by subtracting the unspiked sample concentration from that of spiked sample for each person. Percent (%) difference from the nominal value of 0.145 was calculated and the data presented in box plot for each group of population. Each box presents the mean, standard deviations, and range. Side panel: Comparisons with a control using Dunnett's method.

standards and SCs are within acceptance criteria, (2) patient sample concentrations are in the ranges expected for predosed samples, and (3) postdosed patient sample concentrations are consistent with the values expected for previous pilot study (such as PD profile, dose effect, and recovery to normal after treatment change, if applicable). Data should be evaluated for false positive (specificity) and false negative (sensitivity). For example, the variability of the SCs could reflect the assay noise of incurred samples. This variance should be smaller than that of the difference in disease subject vs. normal (specificity) and that of concentration change due to drug versus placebo effect (sensitivity).

The data mining, interpretation, and linkage of biomarker data to clinical outcome is beyond the scope of this chapter. It should be borne in mind that a useful predictive index of a biomarker is dependent on whether it is used as one of a panel of biomarkers. The statistical power is affected by the sampling number (number of subject and time point) and assay stringency. Therefore, the bioanalytical laboratory should be included in the biomarker team to interpret data use, the model being tested, and the analytical component required for the predictive index desired.

***Regulatory Issues*** Regulatory guidance for bioanalytical validation indicates that the paramount objective of a bioanalytical method validation is to ensure

that the assay is reliable for its intended use (ICH Guidelines, 1994; Shah et al., 1992). This philosophical viewpoint is central to many guidance documents, conference reports, and "white papers" for bioanalytical validation of assays for conventional small-molecule drugs and macromolecular therapeutics (Shah et al., 2000; *Code of Federal Regulations*, 2001a; FDA, 2001; Findlay et al., 2000; Miller et al., 2001; DeSilva et al., 2003). Currently, two basic bioanalytical approaches are being applied to biomarker validation. One is based on the FDA bioanalytical drug assay guidance and is generally referred to as "GLP-like" (*Code of Federal Regulations*, 2001a; FDA, 2001). The second is based on the CLSI and CLIA (National Committee for Clinical Laboratory Standards, 1999; *Code of Federal Regulations*, 2001b). Presently, no regulatory guidance has been given concerning what experiments should be performed and what data are necessary and appropriate for biomarker assay validation (Lee et al., 2007). This has led to inconsistent application of validation procedures and acceptance criteria for biomarkers in clinical trials.

For biomarker assays to be characterized and used for drug development support, they should be GLP-like (Lee et al., 2005, 2006). However, the guidelines must be flexible, to allow assay- and technology-specific applications to meet specific clinical study objectives on a case-by-case basis. Thus, general guidelines for bioanalytical laboratories should be developed to include both good scientific and clinical sense with flexibility to develop specific applications (Lee et al., 2007). At the same time, documentation of change and version control of biomarker methods is important, especially to those who produce elements of the assay or kit.

The FDA has set up an Interdisciplinary Pharmacogenomic Review Group (IPRG) to carry out specific review function for the assessment of biomarker qualification data. The team will evaluate study protocols and review study results of novel biomarkers of drug safety, using appropriate preclinical, clinical, and statistical considerations. The team will then develop recommendations and guidance for the submission of biomarker data, assess the original biomarker context proposal through voluntary data submission (VXDS, where the X indicates a wide range of data sources), and then evaluate the qualification study protocol together with the sponsor to reach a consensus protocol (Goodsaid and Frueh, 2007). Characterization data of novel biomarkers to support efficacy can be categorically in the voluntary data submission, and discussion with the IPRG will clarify the data requirement for drug labeling.

***Documentation*** Documents and data on biomarker characterization to support drug development must be kept in a secure place and made accessible for internal or external audits. All processes and data generation should be traceable. It is critically important to define and document the reference standard. Because novel biomarkers do not usually have established reference standards, characterization of the standard material is dependent on the supplier laboratories from commercial or in-house sources. Documentation such as a certificate or record of analysis and a certificate of stability should be

obtained. If these are not available, at least the source, identity, potency (or concentration), and lot number of the reference material should be documented. A consistent and sufficient supply of the same reference material lot should be reserved and used for the duration of a study and program if inter-study comparisons are intended.

Similar to the reference material, documentation of the source, identity, potency or concentration, and lot number of critical ligand reagents and their stability should be kept. If possible, the same lot of the capturing ligand should be used throughout a study. It is prudent to test for method robustness using multiple lots of reagents during advanced method validation.

***Partial Validation for Change Control*** The time span of biomarker characterization can be a long one. Changes in operators, assay equipment, reagent lots, and a variety of other unforeseen events usually happen and will require additional validation. The significance of the alteration in a method will determine the extent of validation necessary, leading to cross-validation, partial validation, or complete revalidation of an assay to control for changes during or between studies. A validation plan should be prepared for partial validations, describing the intended purpose of change, scope, experiments to be carried out, data comparison, and a prior acceptance criterion for method equivalence. A common set of clinical samples analyzed by both methods can be used to show method equivalence. The sampling size should be powered by statistics based on the desired criterion of acceptance and the method variability. If the method change is expected to be extensive, a new validation would be conducted according to the new analytical procedure, followed by a new written validation report.

## CONCLUSIONS AND PERSPECTIVES

In this chapter we have focused on a discussion of quantitative method validation and assay for biomarker characterization to support drug development using the fit-for-purpose approach. The main processes include: defining the purpose of application, assay development, validation and use meeting the purpose and statistical treatment, and interpretation of analytical and clinical data.

Due to the heterogeneous nature of many protein biomarkers, discrepancies may exist between the endogenous forms and the reference standard. It is important to understand what is being measured and the clinical meaning of the moieties measured as related to disease progression and drug effect. For example, during the course of development of a LBA method, biophysical methods (such as mass spectrometry coupled to ligand binding solid-phase extraction) can be used to select reagents and identify the chemical species being captured in the ligand solid phase.

In addition, there are differences in the standard curve blank control matrix from the intended biological matrix. Parallelism is a characteristic that must

be tested using authentic samples from the target population. Another important consideration is that binding of the biomarker to endogenous binding proteins, receptors, and the xenobiotic drug candidate may cause assay anomaly. Different methods may measure different forms of the biomarker, which often leads to the confounding data in the literature. Specific binding reagents and processing steps can be designed and manipulated to measure "bound" or "free" species of the biomarkers.

In contrast to the exploratory phase, biomarker characterization requires more intense rigor in a quantitative method. For example, method robustness and long-term storage stability must be established; sufficient and consistent supplies of reagents should be assured to sustain the applications through multiple studies; and the same methods should be validated and applied in the participating clinical sites on sample collection and in bioanalytical laboratories on sample assays. Only when a robust method has been established and the assay performance defined, is it possible for the biological variability (clinical variance) to be distinguished from analytical variability and be assigned its clinical significance.

Statistical treatment of biomarker assay performance enables assessing if the method will meet the study purpose before its application. Statistical data from in-study performance continue to add information to the method appropriateness, especially with data from the sample controls, which provide trends in authentic sample stability and reagent lot variability. Data from multiple studies and drug candidates (from the first-in-class to later backups, or to another candidate of related pathways) contribute to the accumulated knowledge of the biomarker.

Whereas the exercise of utilizing biomarkers to support drug development of a single or several candidates can be controlled within a pharmaceutical company, the movement of characterization and qualifications of a novel biomarker will depend on the concerted efforts of multiple institutes/organizations. The collaborative effort of sharing and using the same method and reagents may be a challenge. If different methods are to be used, the data interpretation and comparison will add complexity to this challenge. For example, metaanalysis of clinical biomarker data from publications has been problematic because method details and validation parameters were missing to enable proper comparisons. It will be helpful if a consortium organization will handle data repository and communication (such as standardization of publication) of novel biomarkers. This is the goal of the Biomarker Consortium (launched in October 2006) by the FDA, Foundation for the National Institutes of Health, and Pharmaceutic Research and Manufactures of America through their various working groups.

# MOLECULAR BIOMARKERS FROM A DIAGNOSTIC PERSPECTIVE

Klaus Lindpaintner, M.D., M.P.H.*
*F. Hoffmann–La Roche AG, Basel, Switzerland*

## INTRODUCTION

Molecular biomarkers may be useful in a number of applications, including mechanistic studies, preclinical safety and efficacy testing, early clinical pharmacodynamic assessment, dose-finding studies, and stratification for efficacy or safety and dose determination or dose guidance for a marketed pharmaceutical product. Although applications for a marketed drug product will pose the most demanding requirements in terms of the characterization of the test and its development into a commercially available product, all biomarker tests will need to satisfy certain requirements to be useful for derivation of the information they are intended to deliver.

A broader definition of the term *molecular biomarker* comprises any and all in vitro testing for biologically informative molecules in tissues or body fluids, be they for purposes of diagnosing disease, preventive health screening applications, prognostication of the natural history of a disorder, prediction of likely efficacy or safety parameters of a treatment, monitoring of treatment efficacy, or screening health care product manufacture or processing, including blood products.

*This communication represents the author's personal views and not necessarily those of any of his institutional or corporate affiliations, including F. Hoffmann–La Roche.

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

For purposes of the discussion below, we focus primarily on the diagnostic perspective as relevant to novel biomarker tests that accompany the development of a drug, in particular those that will require the development of a commercially available diagnostic test. Since such tests, which are often referred to as *companion diagnostics*, represent the most demanding scenario, they serve as an example for the spectrum of possible considerations that may be applicable to any diagnostic test—even though, in reality, most tests that add value at various points during the discovery or development of a drug will not need to live up to such scrutiny.

The fundamental question determining whether a biomarker is useful is the added information content that it conveys regarding the question it is intended to answer, and whether or to what extent this information adds value in the treatment of patients. Determination of these parameters will generally require characterization of the test on multiple levels that may be defined, broadly, as analytical and clinical. Analytical performance includes a number of metrological aspects, and clinical performance is largely subdivided into validation and utility.

## ANALYTICAL PERFORMANCE

Describing and characterizing analytical performance is very much oriented toward metrology. The general conventions and standards to consider include precision, trueness, and accuracy, along with a number of other more technical characteristics that describe the performance of a test.

### Analytical Precision and Imprecision

*Precision* is a measure of the random error or variability observed in measurement results and is a product of the sample handling and analytical process. Precision is typically expressed as the standard deviation found in sample results. Precision includes the definitions of repeatability and reproducibility. *Repeatability* is the precision with which, in a series of measurements carried out in sequence, results of a measurement agree with each other. *Reproducibility*, on the other hand, means the precision with which measurements of the same standard specimen carried out not in sequence, but under conditions that differ in some specified way (common examples are day to day, or lab to lab), agree with each other. The difference between actual and perfect agreement of these values is referred to as *imprecision*.

### Analytical Trueness and Bias

*Trueness* describes the closeness of agreement of an average value from a large series of measurements with a "true value" or an accepted reference value. The numerical value that represents the difference between the two is gener-

ally referred to as *bias*. Bias refers to systematic differences between measurement results and the true value of a parameter that is being measured. Bias in measurement results can be introduced in a number of ways, including through sampling, sample handling, sample preparation, matrix interference, cleanup, and determinative processes.

## Analytical Accuracy

*Accuracy* refers to a composite assessment that comprises both random and systematic influences (i.e., both precision and trueness). Its numerical value is the total error of measurement.

## Other Metrics Describing Analytical Performance

Aside from metrics for analytical accuracy, a number of parameters are of importance in defining and/or determining the utility of a particular test:

1. The *limit of detection* (LOD) is the smallest amount of an analyte that can reliably be detected by an assay, with a stated confidence limit. The definition includes a number of different *detection limits* that define different properties of the assay, including the lower limit of detection (LLOD), the instrument detection limit (IDL), the method detection limit (MDL), the (lower) limit of quantitation (LOQ or LLOQ), and the practical quantitation limit (PQL). The detection limits are estimated from the mean of a number of repeated measurements of the blank, the standard deviation of the blank measurements, and a defined confidence factor. The PQL is defined simply as about five times the MDL.

   In practical terms, the *lower limit of detection* is the lowest level of analyte that can be statistically distinguished from the blank (i.e., from background noise). LLOD is a function of the variability of the blank and the sensitivity of the assay. The LLOD is usually considered to be a value that is 3 standard deviations above the mean of the blank. Using this formula, the chance of misclassification is 7%. If 2 standard deviations are used, the chance of misclassification is 16%. Values below the LLOD should be reported as "less than the LLOD value" rather than as a finite value.

   The LLOD can commonly be distinguished from an additional variable that is not assay-specific but instrument-specific. Most analytical instruments produce a signal even when a blank (matrix without analyte) is analyzed. This signal is referred to as the *instrument detection level* or *instrument noise level*. The IDL is the analyte concentration that is required to produce a signal greater than three times the standard deviation of the noise level. Ideally, this would be equivalent to the assay's LLOD (as determined under optimal conditions), but is usually somewhat higher.

2. The *method detection limit* (MDL) is a metric that is similar to the IDL, but is based on samples that have gone through the entire sample preparation scheme prior to analysis, such as extractions, digestions, concentrations or dilutions, or fractionations, as well as interference by other components present in a complex matrix. The *recovery* of an analyte in an assay is the detector response obtained from an amount of the analyte added to and extracted from the biological matrix, compared to the detector response obtained for the true concentration of the pure authentic standard.

   Recovery pertains to the extraction efficiency of an analytical method within the limits of variability. Recovery of the analyte need not be 100%, but the extent of recovery of an analyte and of the internal standard should be consistent, precise, and reproducible. Recovery experiments should be performed by comparing the analytical results for extracted samples at three concentrations (low, medium, and high) with unextracted standards that represent 100% recovery.

3. The *limit of quantitation* (or quantification), also referred to as *lower limit of quantification* (LLOQ), is set at a higher concentration than the LLOD; in the statistical method, it generally is defined as 10 standard deviations above the mean blank value, thus presenting a greater probability that a value at the LLOQ is "real" and not just a random fluctuation of the blank reading. The lowest standard on the calibration curve should be accepted as the limit of quantification if the analyte response at the LLOQ is at least five times the response compared to the blank response, and if the analyte peak (the response) is identifiable, discrete, and reproducible with a precision of 20% and an accuracy of 80 to 120%.

   The LLOQ can differ drastically between laboratories, so another parameter for detection limit is commonly used, the *practical quantitation limit* (PQL). The PQL is commonly defined as 3 to 10 times the MDL.

4. *Selectivity* is the ability of an analytical method to differentiate and quantify the analyte in the presence of other components in the sample. For selectivity, analyses of blank samples of the appropriate biological matrix (plasma, urine, or other matrix) should be obtained from a sufficiently large and representative number of sources. Each blank sample should be tested for interference, and selectivity should be ensured at the lower limit of quantification (LLOQ).

5. The *coefficient of variation* (CV) is a normalized measure of dispersion of a probability distribution. It is defined as the ratio of the standard deviation to the mean. It is often reported as a percentage (%) by multiplying the calculation by 100. The coefficient of variation is useful because the standard deviation of data must always be understood in the context of the mean of the data. The coefficient of variation is a

dimensionless number, so when comparing between data sets with different units or wildly different means, one should use the coefficient of variation for comparison instead of the standard deviation.

## DIAGNOSTIC ACCURACY AND CLINICAL VALIDATION

*Diagnostic accuracy*, determined by a process commonly referred to as *clinical validation*, refers to the degree with which results of a test concur with what would be considered the current gold standard of clinical assessment of the question under study. This may be another biomarker (i.e., an established reference test) or—the real gold standard—a clinical outcome or endpoint, such as survival or death. Accuracy can be expressed through sensitivity and specificity, positive and negative predictive values, or positive and negative diagnostic likelihood ratios. Each measure of accuracy should be used in combination with its complementary measure: sensitivity complements specificity, positive predictive value complements negative predictive value, and positive diagnostic likelihood ratio complements negative diagnostic likelihood ratio [1,2]. All of these parameters are not intrinsic to the test and are determined by the clinical context in which the test is employed. A summary of the characteristics, and the strengths and weaknesses of these metrics, is presented in Table 1.

### Sensitivity

The *sensitivity* ("positivity in disease") of a test is the probability that it will produce a true positive result when used on a diseased population (compared to a reference test or gold standard assessment). For the purpose of biomarkers, this would translate to the probability of, or the frequency with which, a particular qualitative marker, or a certain value of a quantitative marker is observed in the group of people harboring the condition of interest. After inserting the test results into a table set up like Table 2, the sensitivity of a test can be determined by calculating TP/(TP + FN). High sensitivity corresponds to high negative predictive value and is the ideal property of a *rule-out test*.

### Specificity

The *specificity* ("negativity in health") of a test is the probability that a test will produce a true negative result when used on a nondiseased population (as determined by a reference test or gold standard assessment, such as clinical outcome). For the purpose of biomarkers, this would translate to the probability or the frequency with which a particular qualitative marker, or a certain value of a quantitative marker, is not observed in the reference group of nonaffected individuals. After inserting the test results into a table set up like

**TABLE 1 Summary of Characteristics for Various Parameters Used in Describing Clinical Test Performance**

| Metric | Definition[a] | Strengths | Weaknesses |
|---|---|---|---|
| Accuracy | (TP + TN)/N | Intuitive | Depends on prevalence |
| Sensitivity | TP/(TP + FN) | Does not depend on prevalence | Applies only to diseased persons |
| Specificity | TN/(TN + FP) | Does not depend on prevalence | Applies only to nondiseased persons |
| Positive predictive value | TP/(TP + FP) | Clinical relevance | Depends on prevalence |
| Negative predictive value | TN/(TN + FN) | Clinical relevance | Depends on prevalence |
| Positive likelihood ratio | [TP/(TP + FN)]/[FP/(TN + FP)] | Does not depend on prevalence | Applies only to positive tests |
| Negative likelihood ratio | [FN/(TP + FN)]/[TN/(TN + FP)] | Does not depend on prevalence | Applies only to negative tests |
| Odds ratio | (TP × TN)/(FN × FP) | Does not depend on prevalence; combines sensitivity and specificity | Values FP and FN errors equally; not intuitive |
| Area under curve | Area under ROC curve | Does not depend on prevalence; combines sensitivity and specificity | Lack of clinical interpretation |

[a]FN, false negative; FP, false positive; N, sample size; ROC, receiver operating characteristic; TN, true negative; TP, true positive.

Table 2, the specificity of a test can be determined by calculating TN/(TN + FP). High specificity corresponds to high positive predictive value and is the ideal property of a *rule-in test*.

## Positive Predictive Value

The *positive predictive value* of a test is the probability that a person is diseased when a positive test result is observed. In practice, predictive values should only be calculated from cohort studies or studies that legitimately reflect the number of people in that population who are diseased with the disease of interest at that time [i.e., when the prevalence (or incidence, for predictive tests) of the disorder is known]. This is because predictive values are inher-

**TABLE 2 Basic Model for Clinical Test Performance**[a]

| | Gold Standard (Reference Test Results or Clinical Outcome) | |
|---|---|---|
| New Test Results | + | – |
| + | TP | FP |
| – | FN | TN |

[a]TP, number of true-positive specimens; FP, number of false-positive specimens; FN, number of false-negative specimens; TN, number of true-negative specimens.

ently dependent on the prevalence of disease, called the *prior probability*. After inserting results into a table set up like Table 2, the positive predictive value of a test can be determined by calculating TP/(TP + FP).

### Negative Predictive Value

The *negative predictive value* of a test is the probability that a person is not diseased when a negative test result is observed. Again, this measure of accuracy should be used only if prevalence is available from the data. After inserting test results into a table set up like Table 2, the negative predictive value of a test can be determined by calculating TN/(TN + FN).

### Positive Diagnostic Likelihood Ratios

*Diagnostic likelihood ratios* (DLRs) are not yet commonly reported in peer-reviewed literature or in marketing information provided by test manufacturers, but they can be a valuable tool for comparing the accuracy of several tests to the gold standard, and they are not dependent on the prevalence of disease [3]. The *positive DLR* represents the odds ratio that a positive test result will be observed in a diseased population compared to the odds that the same result will be observed among a nondiseased population. After inserting test results into a table set up like Table 2, the positive DLR of a test can be determined by calculating [TP/(TP + FN)]/[FP/(FP + TN)], or it can also be expressed as sensitivity/(1 – specificity).

Useful tests will therefore have larger positive DLRs, and less useful tests will have smaller positive DLRs. An example interpretation of a positive diagnostic likelihood ratio equal to 5.0 is that for every 1% of nondiseased subjects that test as positive, 5% of the diseased subjects will test as positive. DLRs leverage pretest into posttest probabilities of a condition of interest, and there is some evidence that they are more intelligible to users.

## Negative Diagnostic Likelihood Ratios

The *negative DLR* represents the odds ratio that a negative test result will be observed in an diseased population compared to the odds that the same result will be observed among a nondiseased population. After inserting the test results into a table set up like Table 2, the negative DLR for a test can be determined by calculating [FN/(TP + FN)]/[TN/(FP + TN], or as false negative rate/true negative rate.

Useful tests will therefore have negative DLRs close to zero, and less useful tests will have higher negative DLRs. As an example, interpretation of a negative diagnostic likelihood ratio equal to 2.5 is for every one false negative, we observe 2.5 true negatives.

## Receiver Operating Characteristic

The determination of an "ideal" cutoff value of a quantitative test that delivers continuous values is almost always a trade-off between sensitivity (true positives) and specificity (true negatives). As both change with each cutoff value, it becomes difficult to determine which cutoff is ideal. A graph of sensitivity against (1 – specificity) is called a *receiver operating characteristic* (ROC) *curve*. The ROC curve offers a graphical illustration of these trade-offs at each cutoff for any diagnostic test that uses a continuous variable. Ideally, the best cutoff value provides both the highest sensitivity and the highest specificity, easily located on the ROC curve by finding the highest point on the vertical axis and the farthest to the left on the horizontal axis (upper left corner) (Figure 1). ROC curves compare sensitivity versus specificity across a range

**Figure 1** Receiver operating characteristic curve.

of values of a quantitative biomarker for the ability to predict a dichotomous outcome. When the cutoff value for a continuous diagnostic variable is increased (assuming that larger values indicate an increased chance of a positive outcome), the proportions of both true and false positives decrease. These proportions are the sensitivity and 1 − specificity, respectively.

A perfect test would have sensitivity and specificity both equal to 1. If a cutoff value existed to produce such a test, the sensitivity would be 1 for any nonzero values of 1 − specificity. The ROC curve would start at the origin (0,0), go vertically up the *y*-axis to (0,1), and then go horizontally across to (1,1), as shown in Figure 1 (dotted line). A good test would be somewhere close to this ideal.

If a variable has no diagnostic capability, a test based on that variable would be equally likely to produce a false positive or a true positive: sensitivity = 1 − specificity, or sensitivity + specificity = 1. This equality is represented by a diagonal line from (0,0) to (1,1) on the graph of the ROC curve, as shown in Figure 1 (dashed line). The curve for a hypothetical test shown in Figure 1 (solid line) suggests that this marker does not provide a very good indication of the outcome of interest, but that it is better than a random guess.

The performance of a diagnostic variable can be quantified by calculating the area under the ROC curve (AUROC) [4]. The ideal test would have an AUROC of 1, whereas a random guess would have an AUROC of 0.5. The AUROC can be calculated as a sum of the areas of trapeziums. For example, in Figure 1, the area under the curve between points (0.2, 0.5) and (0.4, 0.7) is given by $(0.4 - 0.2) \times (0.5 + 0.7)/2 = 0.12$, or in other words, the difference between the *x*-values multiplied by half the sum of the *y*-values. In the example shown, the AUROC for the hypothetical marker is 0.68. This is interpreted as the probability that a patient who has the disease has a test value greater than that for a patient who does not. Like all summary measures, however, there are confidence intervals around this value that must also be taken into consideration for proper interpretation. The area under the ROC curve has become a particularly important metric for evaluating diagnostic procedures because it is the average sensitivity over all possible specificities.

## Precision of Diagnostic Accuracy

It is important to emphasize that as in other empirical studies, specific values of diagnostic accuracy are merely estimates. Therefore, when evaluations of diagnostic accuracy are reported, the precision of the sensitivity and specificity estimates or likelihood ratios should be stated. If sensitivity and specificity estimates are reported without a measure of precision, clinicians cannot know the range within which the true values of the indices are likely to lie. Evaluations of diagnostic accuracy should therefore be described with the inclusion of confidence intervals.

In the case of agreement with (an)other biomarker(s), the driving factor of such an evaluation may be the replacement of an existing, clinically validated

test with a new one that may be operationally or economically more attractive, or one that may have greater diagnostic precision.

## Odds Ratio and Relative Risk

The *odds ratio* is a way of comparing whether the relative odds of a certain event (e.g., of harboring a certain biomarker) is the same for two groups (e.g., those who have the disease as compared to those who do not). An odds ratio of 1 implies that the presence of the biomarker is equally likely in both groups (i.e., that the biomarker does not distinguish between the two). An odds ratio greater than 1 implies that the biomarker is more frequent or prevalent in the first group, and may thus be a useful test to distinguish between the two groups. From Table 2, the odds ratio would be calculated as (TP × TN)/(FN × FP). Odds ratios are applicable solely to retrospective case–control studies, whereas in prospective studies, randomized clinical trials, or cohort studies, calculation of relative risk is appropriate.

The *relative risk* (sometimes called the *risk ratio*) compares the probability of disease in the biomarker-positive and biomarker-negative groups, rather than the odds. It is calculated as TP/(TP + TN)/FN/(FN + TN), which is the quotient of the positive and negative predictive values. It is applicable only to prospective studies, randomized clinical trials, or cohort studies (i.e., to situations where the incidence/prevalence of the outcome is not biased by retrospective selection). However, in rare conditions (i.e., conditions with low incidence or prevalence), where both TP and FN are very small, the odds ratio asymptotically approaches the relative risk and is therefore sometimes substituted for the latter. For small probabilities, TP and FN are very small compared to TN and FP.

## Translating Different Metrics of Information Content

Academic biomarker research tends to be concerned primarily with the statistically determined reliability of a finding. Thus, if the association of a biomarker with a particular phenotype is reproducible, it is interpreted to convey real biological findings that may be of great interest to fundamental understanding of biological mechanisms, even if the magnitude of effect that can be seen under a particular set of experimental constraints is small. Similarly, the Geoffrey Rose paradox [5] explains that true, reproducible observations may be of great importance from the perspective of public health even if the overall magnitude of effect is modest. Thus, targeted modulation of variables that affect disease risk by small amounts may have important effects if applied to large populations and are thus commonly used to guide health policy. Academic epidemiological research evaluating associations of predictors for outcomes often uses odds ratios or relative risk as its primary parameters for reporting results, particularly in the field of genetic association studies. In complex polygenic diseases, the magnitude of effects commonly found for associations

for individual genetic variants generally ranges between odds ratios of 1 to 2. Demonstrating statistical significance for such modest-sized effects requires usually fairly large studies, particularly if multiple comparisons are made (as is the case with genome-wide association studies).

On the other hand, when tests are to be applied to clinical decision making in individual patients, information content with regard to the magnitude of association becomes critically important. Only reliable tests with an acceptably low rate of false positive and/or false negative results can responsibly be used in this setting. These performance parameters tend to be gleaned most directly from stating sensitivity and specificity (or positive predictive value and negative predictive value), and these are therefore the parameters commonly referred to in clinical diagnostics. In general, tests are not considered particularly useful if the area under the ROC curve does not exceed 0.8, which translates into balanced sensitivities and specificities of about 0.75. On the other hand, a balanced sensitivity and specificity of 0.75 translates into an odds ratio of about 9; if an effect of this magnitude is indeed present, it will be readily recognizable even in quite modestly sized studies.

## CLINICAL UTILITY

The term *clinical utility*, although used widely, is ill-defined. It is commonly used as a synonym for studies of clinical effectiveness and/or economic evaluations. The most basic definition of clinical utility refers to an estimation of the respective benefits and risks resulting from test use. Risks and benefits are, at this higher-level perspective, to be seen as encompassing both medical and economic connotations and considerations, even though the discussion of benefits and risks is often restricted to the former.

As health care payers are becoming increasingly cost-conscious, and reimbursement decisions are being more commonly influenced by medical–economic considerations, clinical utility is quickly becoming the overriding consideration with regard to the introduction of a companion or other diagnostic. This adds significantly to the burden of research and development expenses for diagnostic companies since reliable estimates of clinical utility will usually require prospective, controlled studies in which clinical endpoints are reached and where interventions are or are not guided by testing for the biomarker of interest.

### Medical Considerations

On the level of medical considerations, in the narrowest sense of the term, clinical utility refers to the ability of a screening or diagnostic test to prevent or ameliorate adverse health outcomes such as mortality, morbidity, or disability through the adoption of efficacious treatments conditioned on test results. A screening or diagnostic test in isolation does not have inherent

utility; because it is the adoption of therapeutic or preventive interventions that influence health outcomes, the clinical utility of a test depends on effective access to appropriate interventions, or to the way it can beneficially affect the choice of an intervention. This use of the term *utility* is consistent with standard practice in evidence-based medicine, which focuses on objective measures of health status to evaluate interventions. Clinical utility can more broadly refer to any use of test results to inform clinical decision making. Finally, in its broadest sense, the medical interpretation of clinical utility can refer to any outcome considered important to individuals and their families, as well as to other societal strata.

## Medical–Economic Considerations

If economic considerations are included in the definition of clinical utility, the question of whether the actual medical benefit derived from the use of the test indeed results in good value for the cost incurred becomes part of the consideration. *Value* in this context can be assessed by either cost–benefit or cost-effectiveness/utility analyses. In the case of a cost–benefit analysis, costs and benefits are expressed in the same units of measurement, usually monetary. Cost-effectiveness and cost-utility analyses compare the respective monetary cost of using or not using the test with defined clinical outcomes, either in physical terms or by using an index that also includes quality-of-life aspects.

As summarized in Table 3, when considering such *cost–benefit analysis* to evaluate the utility of a companion diagnostic that aids in the selection of a particular treatment, one would compare the aggregate costs of testing all eligible patients, of treating test-positive patients with the associated therapy, and of treating those that are test-negative with the conventional *standard-of-care* approach against the cost of using the standard of care, without any testing, on all patients. In a cost–benefit analysis, the net (pecuniary) gain or loss of the two approaches would be calculated based on direct medical and nonmedical, and on indirect (productivity) costs of either alternative. As an example, if the test is intended to increase the efficacy of a particular treatment, the cost–benefit ratio may be advantageous if the savings in productivity losses due to faster recovery from an illness based on the test-guided stratification of treatments offsets the added cost of testing and use of test-directed treatment alternatives (which may have a greater direct medical cost than the standard of care). Similarly, if a test is used to avoid serious adverse effects, the cost–benefit analysis may indicate advantages if the cost savings realized by avoiding the treatment of adverse reactions outweighs the cost of testing.

In a *cost-effectiveness analysis*, typically the overall cost per outcome unit (such as relapses or survival years), adjusted for a global quality of life in the case of a cost-utility analysis, is compared among the treatment alternatives. In the case of a companion diagnostic, the incremental cost of using the test in all patients and then treating only those in whom the test-driven therapy is either effective or safe may result in an acceptable cost-effectiveness ratio (as

**TABLE 3 Cost–Benefit Considerations for Companion Diagnostics**[a]

| | Efficacy Marker | | Adverse Reaction Marker | |
|---|---|---|---|---|
| | Direct Costs | Indirect Costs | Direct Costs | Indirect Costs |
| Cost of testing | ↑ | | ↑ | |
| **plus** | | | | |
| Cost of diagnostics-driven therapy in selected group | ↑ Novel, presumably more expensive drug | ↓ Faster return to productivity | — | ↓ No productivity loss due to ADR |
| **plus** | | | | |
| Cost of alternative therapy in de-selected group | — | — | — | — |
| **versus** | | | | |
| Cost of alternative therapy in all, no testing | ↓ Standard of care presumably cheaper | ↑ Later return to productivity | ↑ Cost of treating ADR | ↑ Productivity loss due to ADR |

[a]↑, increased cost; ↓, decreased cost.

**Figure 2** Incremental cost-effectiveness ratio Herceptin/HerCep test.

expressed cost per quality-adjusted years of life) for an expensive novel treatment where a less discerning use of the novel treatment may be associated with an unacceptable ratio based on the inclusion of nonresponders. An example for such an analysis was recently conducted for the case of Herceptin and its companion diagnostic test (HerCep test) (Figure 2). In this example

[6], it could be clearly shown that the use of the test in all patients, followed by a targeted prescription of the new drug only to those in whom it was indicated based on the test, showed an acceptable incremental cost-effectiveness ratio, and one that was clearly superior to a more indiscriminate use of the drug.

Cost-effectiveness calculations are affected by numerous factors, including the prevalence of a (positive) test result which materially affects the choice of therapy, the test performance as outlined above in terms of analytical performance and clinical validity, the context with regard to indication and intended use (see below), the magnitude of the advantage over conventional treatments that the test-guided alternative therapy provides, by the cost of tests and different treatments, and last but certainly not least, by the reimbursement environment, including pricing policies that will differ from market to market.

Yet another way of looking at the question of clinical utility with regard to medical economics would be to calculate the *number needed to screen* (i.e., the number of patients that need to undergo the diagnostic test to achieve a particular outcome in at least one case). The outcome could either be defined as the prevention of a death or as an adverse event. Such a definition could be reached for both efficacy markers (where the choice of a certain drug based on screening may result in more successful treatment of eligible patients, and thus lives saved as compared with standard of care therapy) and—perhaps more obviously—for safety markers where the result would be the avoidance of an adverse event.

## CONTEXTUAL CONSIDERATIONS FOR COMPANION DIAGNOSTICS' CLINICAL UTILITY

While clinical performance, expressed as sensitivity and specificity, is of obvious importance for the utility of any test, it is important to recognize that with regard to companion diagnostics, a set of specific considerations apply depending on the intended use of the test. In this respect, both the clinical indication and the magnitude of expected benefit from the treatment, and the intended use to either enhance efficacy or avoid adverse reactions, are variables that will greatly influence the requirements for sensitivity and specificity, respectively, of the desired test (Table 4).

Thus, on one end of the spectrum, in life-threatening indications (e.g., oncology, HIV) and in the case of a drug that may be lifesaving, and for which feasible alternatives do not exist, an efficacy marker would be expected to show a high sensitivity (i.e., few false negatives, as they would result in inappropriate withholding of the treatment), but may be acceptable at lower specificity (false positives will result, for an otherwise safe drug, in unnecessary and ineffective treatment). In contrast, a safety marker in such an indication would be required to demonstrate high specificity (i.e., few false positives, which again would result in unnecessary withholding of the treatment), while

**TABLE 4 Contextual Considerations Regarding Companion Diagnostics**[a]

| | Efficacy Marker | | Adverse Event Marker | |
|---|---|---|---|---|
| Indication | Sensitivity | Specificity | Sensitivity | Specificity |
| Serious or life threatening | ⬆ | ⬇ | ⬇ | ⬆ |
| Less serious or trivial | ⬇ | ⬆ | ⬆ | ⬇ |

[a]⬆, High requirements, important; ⬇, low requirements, less important.

sensitivity is less important [use of the marker would still be expected to result in fewer adverse reactions (ARs) than would otherwise be encountered; in indications where ARs are often viewed as necessary trade-offs].

On the other end of the spectrum, in more trivial indications where treatment is less urgent, the requirement for a safety marker would be very high sensitivity, as a false-negative test would result in the occurrence of an AR, which in this setting is much less acceptable than in a life-threatening illness. Specificity is less important, as "wrongful" withholding in a condition of modest severity is clearly less of an issue. Conversely, again, an efficacy marker would be expected to show high specificity: If the added cost of the test is to be acceptable in such a condition, it would presumably need to be justified more by cost–benefit considerations that would be set off by inappropriate inclusion in the treatment group of patients with false-positive test results.

One may view these considerations from the standpoint of that old medical principle: first, do no harm. In serious disease, the threat may come primarily from the illness, so harm would more likely result from inappropriate withholding of treatment based on a false test result. In contrast, in less serious disease, harm may, rather, come from inappropriate administration of a treatment, and one would perhaps be more aligned with the Hippocratic principle by avoiding noncritical treatments.

## CO-DEVELOPMENT OF A NEW MEDICAL ENTITY AND COMPANION DIAGNOSTIC

If the label of a new medicine is to include the obligatory use of a test, the manufacturer needs to take care that drug and test are developed in tandem and receive regulatory approval in such a fashion that they can reach the market simultaneously. Authorities are paying increasing attention to the challenges that this process may present. The U.S. Food and Drug Administration has issued a concept paper on "Drug–Diagnostic Co-development" (http://www.fda.gov/Cder/genomics/pharmacoconceptfn.pdf) that specifically addresses this issue. A number of working groups, including

the International Conference on Harmonization, are also currently addressing aspects related to this issue, from coining unified terminology and language around biomarkers and companion diagnostics, to formal issues relating to regulatory submissions and the evidentiary standards that will be required to accept a companion diagnostic as valid and useful.

## CONCLUSIONS

At the transition of a biomarker discovery and assessment program into the development for the use of a biomarker as a clinically applicable decision tool, a number of considerations that are not applicable to the discovery stage must come into focus. Many of them represent well-established concepts in analytical metronomy but are not necessarily familiar to investigators at the cutting edge of biomedical research. It is critical that these concepts be considered carefully, as this will directly influence the feasibility of any biomarker test that is to be used in the setting of clinical practice. Although many of the considerations are of a technical nature, the ultimate driver of such workability is, of course, rooted in biology and in the information content conveyed by the data.

# STRATEGIES FOR THE CO-DEVELOPMENT OF DRUGS AND DIAGNOSTICS: FDA PERSPECTIVE ON DIAGNOSTICS REGULATION

Francis Kalush, Ph.D., and Steven Gutman, M.D., M.B.A.*
*U.S. Food and Drug Administration, Rockville, Maryland*

## INTRODUCTION

The U.S. Food and Drug Administration (FDA) introduced its critical path initiative in 2004 as an effort to stimulate and facilitate the scientific process for the development of new drugs, biological products, and medical devices [1]. The initiative was grounded in the sobering reality that between 1993 and 2003, despite a doubling in research and development spending by both industry and the National Institutes of Health (NIH), the FDA observed a decrease in the number of new drug applications (NDAs) and an erratic but flat curve in the approval of new molecular entities. Of particular concern was the dramatic increase in the developmental cost of new drugs and the high rate of new drug failures occurring relatively late in the developmental life cycle (phase III or phase IV drug failures). The critical path was developed to ensure that FDA fosters a collaborative and robust scientific environment to

*The views presented in this chapter do not necessarily reflect those of the U.S. Food and Drug Administration.

help strengthen the assortment of tools that might be used to bring new medical products to the marketplace in an expedited manner. Since its initiation in 2004, a new office, the Critical Path Office, has been created, a comprehensive and ambitious opportunities list has been generated [9], and numerous collaborative projects and initiatives have been born, all with the singular goal of using good science to address the challenge of timely and cost-effective product development.

With the unveiling of the complete human genomic map in 2001–2003 [2,3] and the development of sophisticated new technologies for molecular diagnostics (including use of microarrays and bioinformatics to create integrated multiplex tests with complex molecular signals), considerable attention has been focused on biomarkers (especially those with a pharmacogenomics base) to help improve drug candidacy and to streamline drug studies.

The introduction of a diagnostic biomarker to refine drug discovery has obvious appeal. Although biomarkers in a broad sense can include both imaging technologies and in vitro diagnostic devices (IVDs), for the sake of this chapter the focus is on the latter. When used clinically, IVDs are subject to the same regulations as those applied to all other medical devices. Both the science and regulation required for proper deployment of these companion diagnostics products is quite different than the science and regulation of drugs. As a result, to bring closely linked products to the market in a timely manner, both FDA and sponsors must work collaboratively to address what may often be dual device and drug regulatory requirements.

## FDA REGULATION OF IN VITRO DIAGNOSTIC DEVICES

A *medical device* is defined as an "instrument, apparatus, implement, machine, contrivance, implant, in vitro reagent, or other similar or related article, including a component part, or accessory which is: recognized in the official *National Formulary*, or the *United States Pharmacopoeia*, or any supplement to them, intended for use in the diagnosis of disease or other conditions, or in the cure, mitigation, treatment, or prevention of disease, in man or other animals, or intended to affect the structure or any function of the body of man or other animals, and which does not achieve any of its primary intended purposes through chemical action within or on the body of man or other animals and which is not dependent upon being metabolized for the achievement of any of its primary intended purposes" by the Federal Food, Drug, and Cosmetic Act [21 United States Code [321] (h)]. *In vitro diagnostics* (IVDs) are defined as reagents, instruments, and systems intended for use in the diagnosis of disease or other conditions, including a determination of the state of health, in order to cure, mitigate, treat, or prevent disease or its sequelae. Such products are intended for use in the collection, preparation, and examination of specimens taken from the human body [21 CFR 809.3(a)]. IVDs are devices, as defined in section 201(h) of the act, and may also be

biological products subject to section 351 of the Public Health Service Act. While drugs are regulated in the Center for Drug Evaluation and Research (CDER) under the provisions of the state law, IVDs are regulated in the Center for Devices and Radiological Health (CDRH) under provisions of the Medical Device Amendments of 1976.

Like the regulation of all medical devices, the regulation of IVDs by the FDA is risk-based with devices classified into low-risk (class I, e.g., adjunctive immunohistochemical stains used in conjunction with standard microscopic analysis to subtype tumors), moderate-risk (class II, e.g., prognosis, monitoring in already diagnosed cancer patients), or high-risk (class III, e.g., cancer diagnosis, screening) categories. The FDA regulatory program is comprehensive and includes requirements for registration and listing of products, for high-quality production using good manufacturing practices, and for postmarket reporting of adverse events. For some class I, most class II, and all class III devices, FDA review is required before a new medical device can enter the marketplace.

- *Class I devices:* typically present minimal potential for harm to the user and the person being tested. They are subject to general controls, which include registration and listing, labeling, and adverse event reporting requirements [section 513(a)(1)(A) of the act]. Most class I devices are exempt from premarket notification (see definition below), subject to certain limitations found in section 510(l) of the act and in 21 CFR 862.9, 864.9, and 866.9. An IVD example of class I devices is complement reagent (21 CFR 866.4100).
- *Class II devices:* devices for which general controls alone are insufficient to provide reasonable assurance of their safety and effectiveness and for which establishment of special controls can provide such assurances. Special controls may include special labeling, mandatory performance standards, risk mitigation measures identified in guidance, and postmarket surveillance [section 513(a)(1)(B) of the act]. Most class II devices require premarket notification. IVD examples of class II devices include glucose test systems (21 CFR 1345), antinuclear antibody immunological test systems (21 CFR 866.5100), and coagulation instruments (21 CFR 864.5400).
- *Class III devices:* devices for which insufficient information exists to provide reasonable assurance of safety and effectiveness through general or special controls. Class III devices are usually those that support or sustain human life, are of substantial importance in preventing impairment of human health, or which present a potential, unreasonable risk of illness or injury [section 513(a)(1)(C) of the act]. Most class III devices require premarket approval (PMA), defined below. IVD examples of these include automated PAP smear readers, nucleic acid amplification devices for tuberculosis, and total prostate-specific antigen (PSA) for the detection of cancer (21 CFR 866.6010).

Laboratory-developed tests (LDTs), in-house tests, and "home-brew" tests are tests developed in a laboratory for use only in that laboratory. Historically, FDA has applied enforcement discretion to most LDTs and not regulated them actively. Instead, FDA has generally chosen to regulate the components of LDTs, such as instruments and reagents. Considerable discussion has occurred over the past 10 years on the existence of two parallel but noncongruent regulatory pathways to market (IVD "kits" vs. LDTs); these have been the subject of a number of reports, including the Task Force on Genetic Testing and the Secretary's Advisory Committee on Genetic testing [4]. The Secretary's Advisory Committee on Genomics, Health and Society (SACGHS) is in the process of discussing the issue of genetic tests with regard to potential scientific or regulatory gaps and is currently seeking public comment on a draft report to the Secretary of Health and Human Services (HHS) on the oversight of genetic testing [5].

## Major Elements of a Submission

Major elements of a submission can be found by browsing the Office of In Vitro Diagnostic Devices and Safety (OIVD) 510(k) data templates posted on the OIVD Web page [6]. These summarize information related to specific cleared products, including the intended use/indications for use, analytical and clinical validation information, device description including platform and software information, information on instrument and software validation when applicable, and labeling (package insert information). IVD labeling is unique among medical devices since it is described specifically in regulation [21 CFR 809.10(b)]. For PMAs, information describing manufacturing, design controls, and adherence to quality system regulations are also needed.

The intended use should specify what analyte the test measures, the clinical indication for which the test is to be used, and the target population for which the test is intended. It should also indicate whether the test is qualitative and quantitative.

Analytical validation includes precision (repeatability and reproducibility), accuracy, limit of detection, interferences, cross-reactivity, software, performance around the cutoff, carryover, cross hybridization, sample preparation/conditions, and assay limitations. FDA recognizes dozens of standards by the Clinical Laboratory Standards Institute (CLSI) to assist companies in developing this information. A list of recognized standards [10] may also be found on the OIVD Web page.

Clinical validation should be established in appropriate clinical studies to support the indication for use and claims of the device. These studies generally need to be provided by the sponsor or, if available, sponsors may also cite applicable clinical literature. For clinical literature to be acceptable for product clearance or approval, the quality must be carefully assessed and the link between the published studies and the device being reviewed must be carefully established. In instances where tests are developed based on sequential use of

training sets followed by independent test validation, the FDA encourages that rigorous and meticulous attention be paid to the training sets used for new diagnostic markers. However, FDA review is focused on the independent validation that supports the merits of the device itself based on feasibility studies and development of a clear hypothesis in a defined population under established conditions of use.

When the system includes software, software documentation including software design, hazard analysis, and complete verification and validation should be provided [11]. Labeling needs to be detailed sufficiently to satisfy the requirements of 21 CFR 807.87(e). Final labeling for in vitro diagnostic devices must comply with the requirements of 21 CFR 809.10 before the device is introduced into interstate commerce. Among the particularly important components of required labeling are an intended use, device description, directions for use, quality control, precautions, warnings and limitations, performance characteristics, interpretation of results, and values expected.

## REGULATORY TOOLS AND SOLUTIONS FOR PHARMACOGENOMICS MARKERS

Over the past several years, the Office of In Vitro Diagnosis (OIVD) has made flexible use of its regulatory tools to help bring important new diagnostics to market. These include the use of the preinvestigational device exemption (pre-IDE process), expedited review, real-time work interactions, and *de novo classification* of new devices into classes II and I under section 513(f)(2) of the FDCA. The purpose of a pre-IDE protocol review with the FDA is to assist the sponsor and familiarize FDA with cutting-edge technology in advance of the submission. Furthermore, assistance may be needed in defining possible regulatory pathways, study design and analysis of complex data, and statistical approaches before initiation. This is a work process performed by review staff in the Center for Devices and Radiological Health at no cost to sponsors with a 60-day time line. OIVD now processes almost 300 pre-IDEs per year and finds that use of this process decreases uncertainty in the review process, provides an early opportunity for question and answers, and drives the least burdensome approach for sponsors.

Both 510(k)s and PMAs for cutting-edge IVDs may also be designated for expedited review if the device is expected to provide unique public health benefits. Expedited review ensures that at every stage in the review process, the device under consideration goes to the front of the review queue. Even so, the outcome of an expedited review, like the outcome of all reviews, will depend ultimately on the quality of the submission.

A subcategory of PMA supplements is eligible for what is known as *real-time review*, which calls for rapid interactive review between the FDA and sponsors. Although OIVD gets only a small number of real-time applications

per year, it has found rapid interactive review with sponsors to be so successful that it has been applied more broadly to review pre-IDEs and IDEs and processing of some devices subject to expedited review. In some cases, such interaction has facilitated review of cutting-edge new products in two weeks or less.

OIVD has also made use of the de novo classification process authorized by section 513(f)(2) of the FDCA. A device that measures a new analyte or has an intended use for which no submission has previously been cleared or classified as a class I or II device is automatically assigned a class III designation, which would require a PMA submission. Under the de novo process, a sponsor that receives a determination that its device is not substantially equivalent may petition for classification directly into class II or class I if it can provide sufficient scientific basis for the FDA to conclude that a reasonable assurance of the safety and effectiveness of that device can be assured without a PMA. In this case, the new device may be tested by the manufacturer in the same way as it would be for a PMA to establish that the test is safe and effective, but the review is performed following the administrative procedures commonly applied to the 510(k) process. As a result, many PMA requirements, including premarket review of manufacturing processes, premarket inspection of manufacturing facilities, and requirements for annual reports, are all not required. Mandatory time lines for review are also shorter (90 vs. 180 days).

For de novo classification requests, OIVD has been able to use clinical data and supportive literature information, current U.S. clinical guidelines and practices, as well as product-specific data generated by the sponsor to conclude that classification into class II is appropriate and to establish special controls. This type of classification occurs more quickly than other classification processes and more quickly than review of a PMA, and the newly classified device not only may be legally marketed but becomes the first predicate device for a new classification, creating a means for subsequent similar devices to reach the market through the 510(k) process. Devices to detect cytochrome P450 DNA polymorphisms, cystic fibrosis mutations, West Nile antibody, breast cancer gene expression signatures, and the hemagglutinin 5 (H5) subtype of influenza are among the products cleared using the 510(k) de novo process and the establishment of special control guidances.

## REGULATORY FRAMEWORK TO ACCOMMODATE CO-DEVELOPING DRUG DIAGNOSTICS

The lifecycle to obtain marketing approval for the development of a new drug is outlined in FDA law and regulation and progresses through a well-defined multistep process: basic research, prototype design or discovery, preclinical development, clinical development (phases I, II, and III), FDA filing/approval/launch, and postlaunch (phase IV).

**Figure 1** (A) Drug and (B) device development pathways.

The development of a new diagnostic also goes through a well-defined multistep process: basic research, feasibility studies, analytical validation, clinical validation, and FDA approval/clearance. The developmental pathways for a drug and device are illustrated in Figure 1. When use of a diagnostic test is identified as important in selecting which patients receive or avoid a new drug or are to be given a higher or lower dose of a drug, the efficacy/safety of the drug becomes inextricably linked to the effectiveness of the diagnostic. Drug performance will only be as good as the ability of the diagnostic to properly select patients for that drug treatment.

Drug performance is judged based on an assessment of the drug to meet appropriate clinical endpoints or responses with a reasonable safety profile. Diagnostic studies are based on demonstrating that a test properly identifies an outcome or target of interest. When the diagnostic is used to detect drug response, the outcome of interest becomes the drug response or avoidance of drug toxicity. The test parameters of interest in the context of co-development with a new drug do not differ from those of ubiquitous interest in the study of a new diagnostic.

Standardized techniques to establishing test performance have been promoted in the literature and in FDA guidances. Clinical parameters of importance include sensitivity—in this case the ability of the test to identify patients who will exhibit the desired drug response of interest—and specificity—in this case the ability of the test to identify patients who will not demonstrate the drug response of interest. Alternative useful techniques include a definition of the predictive value of a positive result (the fraction of test positives who respond), the predictive value of a negative result (the fraction of test negatives who do not respond), or the likelihood ratio of drug response after testing. The hazard ratio (HR) in prospective studies/analysis and the odds ratio (OR) in retrospective analysis could be used when interpreting probabilities in a different context of use.

## CHANGES IN STRATEGIC THINKING

Because there are now two separate medical products under investigation which may have different life cycles, companies involved in co-development are facing new challenges and may have to create complex arrangements that allow for regulatory and business issues to be addressed. FDA is committed to approaching products being submitted as part of a co-development paradigm to assuring that good science and appropriate regulatory thresholds be met but also bringing to bear a regulatory framework that is as flexible as possible.

Companies may either wish to rethink their business models, shift strategies to accommodate new types of products, and change administrative structures to allow drugs and devices to be developed either in parallel or at least in a scientifically streamlined manner. Moreover, companies may be inclined to develop business alliances, seek out business partners and financial solutions to developmental costs that will encourage product development, and demonstrate the proper premium on testing so that value-based reimbursement becomes possible. Some authors have called for health system reforms that promote value-based, flexible reimbursement for innovative diagnostics and therapeutic products, and others have highlighted potential value to creating stronger economic incentives for the development of personalize medicine [7]. As health care costs continue to skyrocket, the role of FDA regulation appears to be a less important barrier to development of product than obtaining reimbursement or widespread clinical acceptance. Increasingly, both third-party payers and health care gatekeepers are demanding studies grounded in evidence-based medicine before making coverage decisions or before choosing to order new tests. There is also heightened interest among third-party payers to performing complex cost-effectiveness analysis to help make payment determinations.

## PATHS IN CO-DEVELOPMENT

There are several major paths of co-developing a drug and associated test: (1) drug and test are developed in parallel (true co-development); (2) drug is developed first, followed by the diagnostic test(s) development (drug rescue in case there are safety issues discovered in phase IV); and (3) the already existing test can be used for drug(s) selection (patient enrichment/stratification). Multiple tests may be developed for the selection of a certain drug, either in parallel with the drug or at a later date. Figure 2 illustrates major drug diagnostics collaboration scenarios.

In the end, regardless of the path taken, co-development results in cross-labeling/relabeling of drug and/or the diagnostics. FDA drug package inserts frequently cite the relevant in vitro diagnostic test(s), and FDA cleared/approved devices reference the targeted drug(s). Table 1 presents current

**Figure 2** Drug-diagnostics collaboration scenarios.

**TABLE 1 Current Pharmacogenomics Examples**

| Drug | Efficacy Test | Safety Test |
|---|---|---|
| Trastuzumab (Herceptin)[a] | HER-2/neu IHC and FISH[b] | |
| Imatinib mesylate (Gleevec)[a] | C-kit IHC[b] | |
| Cetuximab, Panitumumab[a] | EGFR IHC[b] | |
| Imatinib mesylate (Gleevec)[a] | bcr/abl or 9:22 tr | |
| Gefitinib | EGFR mutations | |
| Irinotecan[a] | — | UGT1A1 mut[b] |
| 6MP and azathioprine[a] | — | TPMT |
| 5-HT3R antagonist, codeine derivative | — | CYP450(2D6) mut[b] |
| Warfarin[a] | — | CYP2C9&VKORC1[b] |

[a]FDA drug package insert cites the relevant test.
[b]FDA cleared/approved device in reference to the drug.

examples. This document is intended primarily to provide direction for the development of diagnostics that are used to select or avoid drugs (predictive tests). A predictive test/biomarker would be defined as a single trait or a signature of traits that separates different populations with respect to the outcome of interest in response to a particular (targeted) treatment (e.g., response to Herceptin, Erbitux, Panitumumab).

Predictive tests could be categorized into three classes: (1) a predictive test for efficacy, to identify patients most likely to respond beneficially to a

targeted treatment; (2) a predictive test for safety, to identify patients most likely to respond adversely to a targeted treatment; and (3) a predictive test for dosing, to identify a patient's specific dosing to optimize the benefit of or minimize the risk of a targeted treatment.

Following Sargent et al. [8], a predictive biomarker provides information about the effect of treatment and is useful for selecting patients for the drug. In this document, diagnostic tests are assumed to be predictive biomarkers. However, much of the discussion also applies to a prognostic test or biomarkers defined as follows: A prognostic biomarker (e.g., risk for cancer recurrence) is a single trait or a signature of traits that separates different populations with respect to the risk of an outcome of interest in the absence of treatment or despite nontargeted "standard" treatment.

## Co-Development and Phase I and II Drug Studies

Ideally, when a drug and a diagnostic are to be used in combination, the development of the drug and diagnostic should be coordinated as much as possible. For the drug candidate, CDER requires phase I studies to demonstrate drug safety and phase II studies to confirm proof of concept, determine dosing and expand on drug safety. In cases where biomarkers are being studied for possible use with a drug, the diagnostic work is generally exploratory but, ideally, should include initial biomarker validation.

Phase I and II drug studies do offer opportunities to gather preliminary data about associations between biomarkers and drug use. This information may include descriptive data on prevalence of the biomarker, association with adverse events or the safety profile being identified with early drug use, and/or information on possible ability of the test to predict drug response. In addition, the information gathered helps improve benefit–risk analysis at an earlier stage of development. A number of interesting proposals have been made to streamline the path to market by expanding phase II studies to allow better selection and characterization of biomarkers for drug use. Jiang et al.'s [12] proposed design combines a test for overall treatment effect in all randomly assigned patients with the establishment and validation of a cut point for a prespecified biomarker for identifying the sensitive subpopulation. The procedure provides prospective tests of the hypotheses that the new treatment is beneficial for the entire patient population or that it is beneficial for a subset of patients defined by the biomarker. The good news is that this allows an opportunity to introduce a drug without or with a biomarker as circumstances may dictate. However, the bad news is that each separate hypothesis cannot be performed without a $p$-value penalty, so a recommendation is made that testing for the drug affect in the all-comers population be with $p = 0.04$ and, if needed, follow-up testing in the biomarker positive population occurs with a $p = 0.01$. Proposals have also been made to find mechanisms of adaptive design applying Bayesian statistics to allow phase II and III studies to be performed in a more seamless manner.

*Adapted from Drug-Diagnostic Co-Development Concept Paper (draft).

**Figure 3** Co-development strategy timing.

## Co-Development and Phase III Drug Studies

If a diagnostic is actually intended for use in patient selection, the safety and efficacy of the drug may in fact depend on the ability of the test to identify patients properly. Clinical trials for drug approval are generally multicenter. Therefore, during co-development the test needs to be standardized and a consensus methodology for test validation among the centers should be established. Ideally, analytical validation should be performed prior to phase III trials, so that clinical validation can be established using an analytical robust test.

When the drug approval is contingent on use of the diagnostic, the diagnostic should optimally be studied either at the time of the original phase III study or in a follow-up phase III–like study before drug approval can be obtained. These studies would most commonly be based on an appropriately designed and powered prospective blinded and randomized clinical trial usually associated with drug approvals and validated in follow-up trials. Co-development strategy timing is illustrated in Figure 3.

## Co-Development After Drug Approval

In those cases in which the drug approval is not contingent upon the use of the diagnostic or when changes in drug labeling for improving safety or effectiveness profiles are being requested, studies may be performed during phase IV drug studies or at any interval following drug approval (e.g., postmarket

commitments). In some cases, prospective studies may be needed; in others, use of banked samples from prospective studies, retrospective studies, and/or cross-sectional studies may be sufficient to support diagnostic claims.

If it is not possible to conduct coordinated studies of the drug and diagnostic, the phase III clinical trial may represent the only opportunity available to obtain and bank prospectively collected samples for future diagnostic test study. Particular attention should be paid to ensuring that samples are collected properly with appropriate informed consent to support future bridging studies (e.g., platform change), diagnostic studies, and evaluation of the analyte of interest. The samples collected should be banked in storage conditions that maintain sample integrity. Concerns about any bias, missing samples, or selection in accrual of banked samples should be addressed appropriately.

## INTERCENTER REVIEW CONSIDERATIONS IN CO-DEVELOPMENT

Overcoming potential regulatory barriers to speed up introduction of innovative technologies and products, while ensuring their safety and effectiveness, is a major challenge. Co-development, to be most efficient, requires coordination and harmonization between FDA reviewing centers. The success of this coordination in part depends on the ability of all stakeholders to foster an increase in the dialogue between the FDA and industry and the ability of the FDA to engage sponsors in collaborative discussion early in the process as science develops.

Co-developed products that would be used together may or may not be combination products as defined in 21 CFR 3.2(e).[1] FDA anticipates that many therapeutic drug and diagnostic test products will be marketed separately. For the purposes of this document, co-development refers to products that raise development issues that affect both the drug therapy and the diagnostic test, regardless of their regulatory status as a combination product or as a noncombination product. For example, when co-developed products are considered together, unique questions may arise that would not exist for either product alone. Scientific or technological issues for one product alone may be minimal, but they may have substantial implications for the other product. Also, postapproval changes in one may affect the safety and effectiveness of the other. The FDA has recently established the Office of Combination Products (OCP)[2] to work with sponsors and FDA work groups to ensure that proper regulatory tools are applied to products used in combination and to assist in addressing problems that joint reviews may encounter.

If the diagnostic becomes integral to approval of the drug, diagnostic approval is needed in parallel with the drug. FDA review centers (CDER and CDRH) are willing to work with single sponsors or collaborating sponsors

(drug–diagnostics companies) to coordinate review processes and have in the past had conjoint teams, tandem panel meetings, and same-day approval of linked products. If the diagnostic has broad use not specifically linked to the drug or if the drug has use not specifically linked to the diagnostic, approvals would follow usual CDER or CDRH procedures and timelines.

In some cases, development of a diagnostic may follow development of a drug and be used to refine or improve the safety or effectiveness profile of the drug. CDER and CDRH will work collaboratively with OCP to determine best practices for addressing these situations in a timely manner.

## CONSULTATION PROGRAMS

The parallel development of a drug and a diagnostic is a relatively new aspect of drug development and calls for careful coordination. FDA has three mechanisms for an early interaction with companies about the use of drug–diagnostic combinations. CDER has developed a new approach for data review referred to as *voluntary genomic data submissions* (VGDSs). These submissions can be used throughout this development process to present and discuss data with the agency that are not used for regulatory decision making but could have an effect on the overall development strategy. Such data submitted voluntarily will not be used for regulatory decision making by the FDA and is not included in the evaluation of an investigational new drug (IND), investigational device exemption (IDE), or market application. Both CDER and CDRH representatives participate in VGDSs and will work with the sponsor to identify when pre-IDE interactions for development of the test in conjunction with the drug are advisable.

CDER has also developed a pre-IND process for early interactions with a sponsor to improve a development program and expedite entry into clinical trials. Pre-IND advice may be requested for issues related to data needed to support the rationale for testing a drug in humans; the design of nonclinical pharmacology, toxicology, and drug activity studies, including design and potential uses of any proposed treatment studies in animal models; data requirements for an investigational new drug (IND) application; initial drug development plans; and regulatory requirements for demonstrating safety and efficacy. Pre-IND interactions should be considered as preliminary communications based on early development information and will generally take the form of written comments that may be supplemented by teleconferences or meetings as needed and appropriate.

The pre-IDE process is the term CDRH uses for a voluntary system available to sponsors for protocol review and has already been described in this chapter. Additional regulatory tools that CDRH uses to support introduction of new molecular diagnostics and co-development products are expedite review submissions (the front of the queue), the de novo process for regulating new unclassified devices (first of a kind) and real-time reviews by reducing

regulatory working time and improving the quality of results (see the Section "Regulatory Tools and Solutions for Pharmacogenomics Markers).

By employing these types of review processes, the intent of CDER and CDRH is to provide useful information to sponsors as they work on co-developed products. The FDA is willing to coordinate work between these reviews as appropriate. The FDA recommends that sponsors of new drug–diagnostic products interact early with the FDA to determine best practice information and current scientific and regulatory thinking.

## SUMMARY

One of multiple important parts of the critical path initiative at the FDA has been a growing interest and attention to the issue of biomarkers, particularly with regard to the role they play as tools to aid in development of drugs and other new therapies. The FDA appreciates that the coordination of reviews across these two product lines may be challenging and has both administrative and regulatory tools in place that can contribute to review successes for these products. Scientific models for optimal evaluation are currently a matter of great interest and discussion at the FDA, and scientists in all three centers regulating human products (CDER, CBER, and CDRH) have had multiple interactions with stakeholders and sponsors of new technologies. It is our belief that the FDA is well positioned to help foster the use of this new technology. We believe that the challenge at hand is taming the science itself and that the FDA can in a nimble manner review new products, assure they are safe and effective, and bring them to market in a manner consistent with the precepts of the critical path program.

## NOTES

1. Under 21 CFR 3.2(e), a combination product is defined to include:
   (1) A product comprised of two or more regulated components, i.e., drug/device, biologic/device, drug/biologic, or drug/device/biologic, that are physically, chemically, or otherwise combined or mixed and produced as a single entity;
   (2) Two or more separate products packaged together in a single package or as a unit and comprised of drug and device products, device and biological products, or biological and drug products;
   (3) A drug, device, or biological product packaged separately that according to its investigational plan or proposed labeling is intended for use only with an approved individually specified drug, device, or biological product where both are required to achieve the intended use, indication, or effect and where upon approval of the proposed product the labeling of the approved product would need to be changed, e.g., to reflect a change in intended use, dosage form, strength, route of administration, or significant change in dose; or

(4) Any investigational drug, device, or biological product packaged separately that according to its proposed labeling is for use only with another individually specified investigational drug, device, or biological product where both are required to achieve the intended use, indication, or effect.

2. Contact information and information on combination products and intercenter review processes may be found on the OCP Web site: http://www.fda.gov/oc/combination.

# IMPORTANCE OF STATISTICS IN THE QUALIFICATION AND APPLICATION OF BIOMARKERS

Mary Zacour, Ph.D.
*BioZac Consulting, Montreal, Quebec, Canada*

## INTRODUCTION

> Learning how to apply statistical analyses … may take a lifetime of trial (and sometimes error), as it has done in the author's case. There is no evidence that biomedical investigators of the present generation are on a steeper learning curve. [1]

Sitting in the Drill Hall at the University of Toronto with row upon row of shifting, sighing, and coughing co-sufferers, cold fingers clutching one of my two well-sharpened HB pencils while I carefully write out each step of my standard deviation calculation. Statistics 101 Christmas exam. One finger rasping down rows and across columns of tables, $p$-values, degrees of freedom, these are the memories I share with countless scientists who have studied statistics in preparation for their research careers. Although I left that course and others with respectable marks and a seemingly clear understanding of the null hypothesis and the normal curve, I found myself some years later, scratching my head as I considered a sheet whose bland columns of numbers belied the painstaking hours spent injecting, isolating, pipetting, incubating, and centrifuging, from which they had been distilled. Looked at one way, it seemed

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

to suggest one thing, but was that the correct approach? Looked at another way, the picture was different. The conclusion to be drawn would influence the direction that the entire project would take.

How to apply the right statistical test correctly to a particular research question, given the many choices, assumptions, and caveats, is not always obvious; indeed "gross misunderstandings of the purpose and functions of statistical analysis are apparent in applications to research grant-giving bodies and ethics committees, in manuscripts submitted to journals and sometimes in published papers" [1]. In fact, there seems to be a growing field of forensic biostatistics, pointing out data analysis errors that have crept into respected publications [2–4]. This is not surprising, considering the advent of genomics, proteomics, and other-omic-style research, in which the ability to produce huge quantities of complex data are outstripping the common biologist's understanding of the mathematical issues concerning its interpretation.

Scientists focused on biomarker research in the drug development industry face an additional set of challenges, where the pressures of the business world to use less time and fewer resources, to focus only on the immediate goal, and to quickly release positive findings to investors or other onlookers are often at odds with the expert, thorough, and careful consideration that the more challenging research problems may require. Understandably, biomedical scientists who are often highly expert in their scientific discipline are not necessarily so in the mathematical issues underlying analysis of their data, and many are also without the luxury of a biostatistician with whom to consult at times of indecision. Although some lucky others may feel that there is no need to master the field when they can simply rely on in-house expertise, it is important to recognize that a working knowledge of the factors affecting data analysis facilitates better communication between the statistician and researcher, which, in turn, generally leads to better research design. Furthermore, the question of how to interpret data wisely is not limited to applying the correct statistical test in the correct manner, but also includes understanding the limits and pitfalls of the technical procedures used to generate the data. In this regard, biostatisticians, too, face challenges, such as being unfamiliar with or intimidated by the rapidly evolving and complex technical methods used in the lab. As so well voiced by Ransohoff [5], "how well do biologists … appreciate the nature or seriousness of problems that can be introduced by methods of handling data … ? How well do epidemiologists or biostatisticians understand technical details of specimen collection, handling, and analysis in a way they can use to anticipate and manage specific sources of bias?"

In addition to an understanding of both technical and mathematical issues, there is a third element important to teasing out the elusive meaning of the data, which I like to think of as the HP factor (Hercule Poirot, that is). Born of intellect and experience, modeled by a higher-order view, a wider vision of extraneous factors that may play roles in the outcome, infused with a measure of skepticism and questioning of assumptions, this factor may more commonly be known as judgment.

Now, I sincerely hope that I am not marked, Rushdie-like, by the statisticians guild for this comment, since this softer science is undoubtedly in the realm of the subjective, and as such, in danger of being classified in the same bin as bias, data selection, and the bubonic plague. To my mind, however, judgment is critical to the success of most endeavors, including data evaluation and statistical analysis. Even though the rules of application of such analyses may be straightforward (in our day, in fact, completed for us by a simple twitch of an index finger on a mouse), understanding potential errors in our data and/or determining which of many analytical possibilities best fit the situation presented by our own experimental paradigm and data set are not, and this is where judgment often comes in.

There is certainly a large mass of statistical reference material already published and available to answer questions that most biologists might have, however, most texts and articles focused on statistical analysis issues are written by, well … statisticians. This is a good thing, of course, but sometimes brings with it the negative corollary of a specialized dialect and viewpoint. Joe or Josephine Biologist may find these, at best, difficult to adapt to their own needs, or, at worst, frankly unintelligible.

This chapter is addressed to fellow Joes and Josephines. It is written in plain language by a nonstatistician who has often grappled at the interface where experimental results are transduced through an intermediate state as digits, before manifesting themselves, newly metamorphosed, into conclusions that flutter their wings right into our collective scientific knowledge database. Whereas some basic statistics explanations may embellish its text, this is by no means intended to serve as a statistics manual, nor to explore the many intricacies of the field; in fact, statisticians may well be appalled by its gaps and oversimplifications. The publisher, on the other hand, is likely to be pleased at the paucity of equations, since it is common knowledge in the industry that book sales drop with each equation in a text. This chapter addresses data analysis issues pertinent to biomarker research in drug development. More specifically, it is intended to clarify some common misconceptions or confusion concerning which situations are appropriate for alternative choices of statistical analysis and to integrate statistical issues with nonstatistical issues that also affect our data interpretation.

## FUNDAMENTALS

### Is That Significance Significant? (And Conversely, the Significant Insignificance)

Statistics texts all deal with the issue of type I and type II errors, or, respectively, the false finding of a significant difference where none exists and the false finding of no significant difference where one indeed exists. They seem invariably to omit mention, however, of how a statistically significant

difference that truly exists and is truly shown can yet remain truly irrelevant. This particular possibility gets no press time in statistics manuals because it remains in the realm of that softer science mentioned above, judgment.

As trained scientists sensitized to the dangers of making inferences based on anecdotal or potentially chance findings, we seem as a group to have acquired the tendency to overexalt the statistically significant finding when it makes its appearance. A $p$-value of 0.05 or less has become our holy grail, the golden chalice that shines from the paragraphs of our grant and investigational new drug (IND) applications, presaging, we hope, the sweet wine to spill forth from them. This, of course, is not unnatural when one considers how often we are faced with budgetary or time constraints on the number of subjects that can be tested and therefore on the ease of statistically confirming such differences when they truly exist. The converse situation of which we need to be mindful, however, is that with enough samples being evaluated, even tiny differences can be statistically significant, and furthermore, even differences that are not tiny might still not be relevant. What constitutes a "significant" increment of an analyte, in the physiological or clinical sense, is likely to vary with the situation; it is not necessarily on the same scale as a statistically significant increment. An additional point to consider, addressed below in the section on measurement error, is whether the magnitude of a statistically significant difference surpasses the magnitude of inaccuracy of measurement.

A qualitative judgment on the significance of significance, rather than simply adjusting our blinders to keep out the sun while logging $p$-values, is certainly worth a moment of silence on our parts. Furthermore, the converse case is also relevant; for example, what if one's inner Hercule is suspicious that a clinical significance may be lurking behind the harmless façade of $p > 0.05$?. How could we reconcile the lack of statistical significance in that case? One possibility is that too few samples were evaluated to achieve the statistical power to reveal significance (discussed further later in the chapter). Another is that part of the group of samples tested reacts differently than (an) other part(s), resulting in a total effect across the disparate subgroups that does not reach statistical significance, even though it reflects a clinical situation of great significance.

The latter concept is central to the development of personalized medicine, an emerging field that seeks to improve disease treatment by targeting molecularly distinct subpopulations within a given group, such that response rates to treatments are increased and the administration of ineffective and potentially toxic treatments to inappropriate individuals is diminished. As an example, selection of breast cancer patients according to *ErbB2* tyrosine kinase status has had a significant impact on management of the disease; moderate, but significant, response rates to *ErbB2*-targeted antibody therapeutics in some studies might have been overlooked had study groups not first been selected for its overexpression [6]. Some basic concepts concerning statistical methods of relevance to pharmacogenomics are discussed later, in addition to some of the common errors in their application.

## Air the Error

Because statistical descriptions and inferences are based on probability, a certain amount of chance (random) error is always inherent in any statistically based conclusion. This error is routinely quantified by upper and lower confidence limits and mentioned in results sections. Unfortunately, such routine error expression seems to induce a false sense of security in readers that *all* the error inherent in the results has been taken into account.

In fact, there are numerous sources of nonrandom error, generally covered by the blanket term *bias* (i.e., when subjects, specimens, or data in the groups being compared are inherently different or are handled differently in a way that systematically introduces a signal into data for one of the groups compared). Differences such as types of tubes used or length of time until spinning or time samples are maintained frozen prior to analysis would fall into this category. Bias has been deemed such a serious problem in nonexperimental research that some experts consider such studies guilty of bias and erroneous results until proven innocent [7]. The term *nonexperimental research* refers to research where the effects of some perturbation to the system are not being tested, but rather, information is simply gathered (i.e., in epidemiological studies) or quantified (i.e., in laboratory analyses, such as most proteomic analysis). Bias is also a serious and often overlooked problem in experimental research [i.e., where effects of deliberate maniuplation of (a) variable(s) are tested]. A recent perspective article on how potential flaws in preclinical research may play a major role in late-phase drug failures discusses this in detail, particularly as it relates to animal models [8].

Measurement imprecision, included by some under the term *bias*, but by others considered separately, constitutes an additional significant source of error. In the case of continuous data quantifications, although measurement error almost always occurs, it is almost never quantified, or at least such quantification is in no way accounted for in the result reported. In the case of noncontinuous data, such as in diagnostic tests that may generate a yes/no dichotomy, measurement error can have a different but equally profound effect, potentially contributing to false positives or negatives.

***Continuous Data Quantifications*** Every assay result is only the best approximation to the true value that a particular assay is able to produce. This is readily acknowledged by all, and, in fact, it is standard practice in drug development to quantify the inaccuracy of assays using known amounts of a reference standard. How the quantification should best be accomplished is beyond the scope of this chapter, but the total error approach wisely incorporates both the components of random error and bias/measurement error in a single measure and is discussed further elsewhere [9–11].

Despite the depth of consideration given to measurement error, there appears to be an element of lip service to its acknowledgment, since error quantifications are generally used only to determine acceptance or rejection

of an assay's results, rather than to modify or qualify in any way the numerical result produced by the assay. Measurement error is thus consistently brushed under the carpet, with results often reported in ways that dramatically overstate their precision. As an end result, differences from one measure to another in some cases become infused with spurious meaning, when they actually represent nothing more than noise in the signals. One can only speculate on how many drugs that failed during late-phase trials might never have gotten that far had the measurement error in their "promising" preclinical results been accounted for in the data analysis.

Sometimes measurement error is compounded dramatically by introducing more than one erroneous measurement into a final calculation of the result, and again the norm is to ignore this inflated error rather than account for it in the results reported. Let us consider the example of a clinical trial examining the effect of a treatment on the activity of a disease biomarker in white blood cells. In this example, two assays are required: one to quantify the disease biomarker in a lysate prepared from the cells, and one to quantify the amount of protein that was culled in each cell preparation. The activity result from the first assay is then normalized against the protein result from the second assay, to give an activity per mass of protein as the final assay result. Looking more closely at the potential error in this example, we should note that standard acceptance criteria for bioassays generally include specification that a certain level of demonstrated measurement error will be considered acceptable, with data still included "as is" in the analysis. Assuming a typical acceptance criterion of up to ±20% inaccuracy, two measurements of a single identical sample of true value $X$ could therefore quantify as differing from each other by 40% of $X$, and no one would raise an eyebrow. In fact, Example 1 shows how once you account for the compound error of the two assays in

---

**Example 1.** One assay for enzyme activity and one for protein content of sample are performed, with the final activity reported as per mass of protein. Assuming ±20% measurement inaccuracy in each of the two assays, we see that if patient A has a true activity of 10 activity units, acceptably accurate activity assays would reveal values of 8 to 12 units, and each milligram of protein would be quantified as 0.8 to 1.2 mg. Therefore, within each assay, an identical sample could have acceptable measurement error, resulting in a 150% increase of one value relative to the other (12 units/8 units, or 1.2 mg/0.8 mg).

Normalizing enzyme activity units to milligrams of protein inflates this possible discrepancy between two identical sample results from 150% to a 220% apparent increase in one sample versus another; that is, the most extreme acceptable values from each assay, normalized against each other, would be 8 units/1.2 mg and 12 units/0.8 mg, for a final resulting range of 6.7 to 15 units/mg as possible results from replicate aliquots of the same sample.

---

this example, two assay results showing a 220% increase in one sample's final result versus another are possible when the two actually are replicates, having an identical amount of the biomarker.

This example demonstrates the compounding of only two measurement errors. Imagine the case when more measurements go into a calculation, each having its own error: for example, when using reporter gene induction in a cell-based system as a model of induction of an in vivo response. In this case there are four measurements that need to be done to control properly, each with its own measurement error range: the reporter gene expression in transfected cells challenged with the experimental treatment, its expression in transfected cells challenged with only the vehicle in which the treatment compound is dissolved, and those same two conditions in cells that were transfected with empty vectors (as a control for the effects of the vector backbone on the system). All too often researchers using models of this sort tend to "simplify" by expressing induction of reporters as simply a fold-increase over the vehicle effect, essentially pretending that the complex and compounded error does not exist.

***Noncontinuous Data*** Measurement error can also have an important effect on noncontinuous data, an effect which, as noted above, is discrete from random error and is rarely taken into account. In this case, misclassifications can occur, such as false negatives or positives. We can all imagine the personal impact of such misclassifications, such as being falsely diagnosed with a deadly disease, or conversely, not receiving appropriate treatment because of a false-negative test result. Misclassification errors also decrease the power of studies to detect significant differences and have the potential to obscure or even falsify study results, leading to equally devastating poststudy impact on a much wider scale.

For example, successful efforts to develop an effective vaccine for malaria, considered to be the deadliest pediatric disease, have been hampered by measurement errors leading to misclassifications. In this case, the fact that vaccine efficacy (VE) is a ratio of the number of infected, vaccinated persons over the number of infected, nonvaccinated persons gives rise to the misconception that false-positive or false-negative diagnosis in the numerator and denominator will cancel out or balance. Actually, since measurement error increases as the lower limit of detection is approached, a partial effect of vaccination causing lower-level signals at the time of measurement (such as a slowing of parasite growth, the biomarker for VE), can lead to systematic error in the measurement of the test group that is not matched in the control group, and an overestimation of VE [12].

The end effects of misclassification error of this sort can vary substantially, depending not only on the goal of the testing and the decisions that are dependent on it, but also on the overall frequency of the disease being studied. For instance, elevated false-positive rates for a test may have a huge impact in the case of rare diseases, and conversely, elevated false-negative rates may have

a bigger impact with very common diseases. Example 2 shows that if a test for rare disease $X$ (occurring in 1 in 1000 people) gives 99% accurate positive results in people who truly have the disease and 95% accurate negative results in people who truly do not have it, any positive test result it gives will be false in 98% of the cases.

---

**Example 2.** A diagnostic test has the following known accuracy: It returns a positive result in 99% of patients who truly have the disease and a negative result in 95% of patients who truly do not have the disease. The disease is rare, occurring in the general population at a rate of only 1/1000 people. Although you have no known predisposition or reason to think you have the disease, you decide to get tested and are shocked to learn that the result has come back positive. What are your chances that the diagnosis is actually a false positive?

$$\text{False positive probability} = 1 - \text{true positive probability}$$

$$\begin{aligned}\text{True positive probability} &= \frac{\text{probability of true positives}}{\text{total of true and false positive probabilities}} \\ &= \frac{0.99 \times 0.001}{(0.99 \times 0.001) + (0.05 \times 0.999)} \\ &= 0.019\end{aligned}$$

$$\text{False positive probability} = 1 - 0.019 = 0.981$$

Your chances are about 98% that the diagnosis of positive is false.

---

The test would have to be 99.9% accurate for negative results before it would have a zero-rated false-positive detection rate. Whereas, intuitively, one might think of 95% and 99.9% accuracy as both sounding pretty good, you can see that the seemingly small gap between them could have a surprisingly important impact.

### What to Do?

Samuel Taylor Coleridge once said that literary reviewers are usually people who would have been poets, historians, and biographers if they could, but having tried their talents at one or the other, and failed, they turn to critics. As in other areas of life, with the issue of measurement error, too, it is much easier to be a critic than to do something well oneself. What should one actually do? This is a very good question indeed, and, feeling a little uncomfortable under Samuel's gaze from the sentence above, I shall attempt to come up with some useful suggestions.

First, the appropriate approach is likely to vary according to the situation, and the most crucial issue to consider when choosing an approach to dealing

with measurement error is the potential risk of the erroneous measurement to the end user of the drug, device, or process under study. Experiments and/or data interpretation should then be designed to err on the side of caution, if risk is an issue.

Other key determinants may include practicalities such as resources and time available to approach the problem, and questions of clinical or physiological relevance of the potential error margin, thresholds, or measurement ranges of interest. If, for example, a 10- to 100-fold increase in biomarker expression would be required for clinical relevance, and the maximum estimated measurement error is in the range of less than threefold, perhaps there is no issue. The discussion above, concerning whether significant differences are clinically relevant also applies to the relevance of measurement errors.

If measurement error is of a magnitude that could be clinically relevant, its quantification becomes more important. Perhaps because of the status quo of ignoring measurement error quantification in biomedical methods (for which, after all, error quantification is much more challenging than for analysis of less complex models), this is not a widespread practice in the drug development industry. One way of acknowledging this error while avoiding complex quantifications might be to use the definition of maximum allowable measurement error that is already made routinely for the purposes of acceptance criteria as a threshold of level of difference, below which results would either not be considered to reflect anything but error, or would be more carefully scrutinized in some predefined way. In other words, if you have determined that up to a doubling in endpoint values in a pretreatment versus posttreatment sample could be attributed solely to compounded measurement error rather than to treatment per se, one might decide not to consider effects to be a result of treatment unless they surpass this measurement error threshold. Of course, the fact that a method has been validated according to across-the-board standards such as having better than 15% or 20% total error does not mean that it actually produces results that are this far from the nominal values of the reference standards, but merely that it may do so at times, and that results of assays where these limits are exceeded will be rejected from the study. Error quantifications may well indicate much less error than the maximum allowed for assay acceptance, so given the circumstances it may be worth putting the time in to determine what the actual error is rather than simply assuming that the worst possible error has always occurred. Actual error might be revealed by data mining from previously amassed quality control data and/or on a per-batch basis using internal standards, for example. In these cases it is as simple as quantifying the proportional values obtained for accuracy rather than simply noting a pass or fail.

In the case where biomarker analysis involves more complex sources of error than a single or a few analytical assays (such as for epidemiological studies or metaanalyses to qualify particular biomarkers for their intended use), more complex uncertainty quantifications would be required. Various such methods are available, including Bayesian [13] and Monte Carlo simula-

tions [14]. Bayesian approaches, which stem from an alternative view of probability compared to the more common frequentist inferential statistics, are touched upon further later. Monte Carlo simulations represent the brute-force type of computation, basically executing a huge number of possible permutations using random draws from all the potential inputs, so as to spit out a final probability function (made up of all the output values from the various random inputs) that comprises the compound error from all the unknown inputs. In a simple example, consider the film *Groundhog Day*, where a man woke every morning to find that it was the same day as the one before. The film consisted of this man going through his interminable repeated days, making different choices when the fixed events of the day occurred, as they did every day; you can think of this man as being stuck inside a Monte Carlo simulation (well, a simple one, since his own behavior choices were the only independent variable with randomly chosen modifications; the range of outcomes were consequences of his varied choices from that one variable). In questions of compound error, of course, there would be many more variables, also all being sampled randomly over and over again. One advantage of choosing a Monte Carlo approach to resolving complex error sources should your experimental paradigm present them, is that user-friendly software is readily available, due to its common use for risk analysis in financial and engineering applications.

Once measurement error has been quantified, by whatever means, error distributions could be used to express uncertainty limits around results, analogous to the random error-related confidence intervals common in statistical analyses. These would help to clarify how much of the apparent differences between sets of results might be an artifact of the measuring tool(s) and not necessarily an effect of the treatment that one wishes to measure. In many cases, such as the reporter gene model example above, literature search will reveal readily applicable statistical models for specific types of assay that incorporate compound sources of error into the calculation of statistical significance of differences [15].

Phillips and Lapole suggest a much simpler approach to partially quantify method error uncertainty without any complicated analysis [16]. Like Pablo Picasso, who once said it took him his entire life to learn how to paint like a child, these authors advocate a return to earlier ways: in this case, the grade-school lesson of rounding figures. Rounding can adjust the measurement scale to reflect the limitations of the measurement error. In their words: "Rounding does not create imprecision—the imprecision exists even if we do not accurately report it." Thus even though the measurement instrument may spit out values with several decimal places in them, samples with results in the range of 100 for a test demonstrating 2% inaccuracy (i.e., 98 to 102) might better be reported rounding to the nearest 5 rather than even to 1's, let alone the decimal points reported by the instrumentation.

Apart from attempting to quantify the error, contain it within a wider measurement scale, or set thresholds of interest that exceed it, as discussed

above, we should also not forget to implement strategies to reduce it, when it is possible to do so. For instance, internal controls such as reference standards or paired samples can reduce the impact of the between-assay variance proportion of measurement error.

For noncontinuous data, misclassification rather than numerical differences are the end effect of measurement error. In this case, a suggested approach to avoid the negative impact of measurement error might be to assume that error will happen, and design studies to have higher power from the beginning, in order to minimize the impact of error on the power of the study. Statistical tests for noncontinuous data are already inherently less powerful than those for continuous data, and a lower initial power level in the experimental design can further magnify the impact of measurement error. For example, Gordon and Finch illustrate how the same misclassification error rate causes much more power loss in a study that has lower power to start with than in a study that has higher power to start with. In their example, given exactly the same error rate, if the study is designed to have 99% power, it ends up with 95.5% after the error is taken into account, whereas if it is designed to have 80% power, it ends up with only 65.4% [17]. Therefore, specifying a higher power in the experimental design gives an advantage of robustness to the obscuring effects of misclassification error. In real terms, designing an experiment with higher power most often translates into recruiting more subjects; these authors advocate that "paying the cost up front" strategy.

## Guilty by Association (and Other Misuses of Correlation Analysis)

"Statistics show that of those who contract the habit of eating, very few ever survive." This William Wallace Irwin quote [18] may bring a small smile to your lips. Should we conclude that eating is a bad habit that causes death? Ridiculous, right? Especially for well-educated biomedical scientists. How about this one: "Greater adiposity is associated with lower everyday physical functioning, such as climbing stairs or other moderate activities, as well as lower feelings of well-being and greater burden of pain" [19]. This quote from a respected medical journal does not seem quite so ridiculous, does it? Whereas the first one is clearly a joke, we might be tempted to nod our heads at the second and experience discomfort in direct proportion to the increases we noted over the past few years in our own level of adiposity.

If we take a closer look at both quotes we will notice that neither author actually claimed a cause-and-effect relationship. As we all know, however (especially those employed in the marketing department), just putting them together in a small room can't help but to make everyone jump to conclusions. The strength of an association is indeed appropriately quantified by correlation analysis, but this analysis should not be misinterpreted to infer causation. Zou et al. hit the nail on the head when they note that rather than being misused to test hypotheses, correlation analysis should serve to *generate* them [20].

The fact remains, however, that correlation is very commonly used to suggest that A causes B, or as in the second example above, being fat causes lower physical ability to function and lower feelings of well-being. Such guilt by association certainly is one possibility, but another possibility is that B causes A, or having lower ability to function and poor self-esteem induces weight gain. A third equally plausible hypothesis is that another cause or set of causes is (are) responsible for both the poor feelings/abilities and the weight gain. A fourth is that the observer has just observed and documented the effects of coincidence; if an insufficient sample number were examined, for instance, a fluke might be documented. Even with larger sample numbers, statistical conclusions are always subject to chance, with the type II error (or *p*-value) describing the percent chances that the "significant difference" is actually just due to chance.

Some extra consideration needs to be given to this when choosing an appropriate biomarker for one's particular purposes. Biomarkers are, after all, by definition, a marker for something else, or an associative entity. If a particular biomarker has been qualified properly, its association with the disease of interest will not be due to chance, but that still does not imply causation. Whether a marker is simply associated, is a cause or an effect of disease, or is a cause or effect of something else causing a disease needs to be considered carefully in the experimental design. The issue of what considerations are important to determine causation is discussed in a landmark paper by Hill [21]. The reader is further referred to an interesting perspective commentary on this subject by Phillips and Goodman [22].

A further frequent misuse of correlation is to test agreement between methods. As pointed out by Bland and Altman [23], even poorly agreeing methods can produce quite high correlations, and for methods to be in perfect agreement their results would plot against each other along the line of equality, whereas results plotting on any straight line would give perfect correlation. Furthermore, the test of significance may show that the two methods are related, but this is irrelevant to the question of agreement, and indeed, it would be amazing if two methods designed to measure the same quantity were not related. One can almost hear their teeth gnashing as they bemoan, "Why has a totally inappropriate method, the correlation coefficient, become almost universally used for this purpose?" It seems clear that this is a case of copycat crime … perhaps a case for the remarkable Hercule Poirot?

## Checking the Dessert Menu First

In much the same way that Hercule Poirot might consider the temptations of the dessert menu before settling on his choice of main courses, we all need to consider potential data analysis issues before settling on our experimental design. Some questions need to be asked long before the data are in hand. For example:

1. Is the assay to measure the biomarker as good as it can be, or the best type of assay given the circumstances? Can you make it better? All assays have error, but the more you fine-tune the accuracy, precision, specificity/sensitivity, and robustness via appropriate optimization, the more your result will reflect for you the marker you wish to measure rather than the shortcomings of your technique. Assay optimization is beyond the scope of this chapter, but should definitely be completed before starting the study. Assay-specific parameters such as accuracy, precision, and specificity of the measurements all have a direct impact on the uncertainty of the statistical analysis outcomes.
2. Have you chosen the best biomarker, or should you rethink from the bottom up? To evaluate this, you must be well aware not only of the qualification that a biomarker is relevant, linked appropriately, and specific to the pathology of interest (important issues, beyond the scope of this chapter), but also of quantitative issues of what to expect in the sample and control groups you have chosen.

   If one wishes to use a biomarker to differentiate between normal healthy persons and those with a disease, for example, one of the many questions to be considered prior to deciding which indeed is the most informative biomarker for the job concerns the potential degrees of measurement between them. In many cases the biomarker of interest is present in normal healthy persons as well as in those with disease, but with different typical levels in the two populations. In this case it is very important to establish a priori the descriptive characteristics of the two groups in order to define what a clinically relevant treatment effect might be and how one might judge that such an effect occurred. Published literature, unpublished previous data, and pilot studies all provide potential resource material for defining these descriptive characteristics and should be evaluated carefully in advance. Since both populations will present with a range of values, relevant descriptive characteristics include not only mean values, but also the variances, ranges, and the difference between the population distributions (or extent of overlap, if that is the case). One should consider that the biomarker that is more consistent in its levels (i.e., less variance) may be a better choice than one that shows bigger mean differences between populations (but higher variability from person to person within a group). In the latter case, the variability can translate into overlap of two populations, which can be quite a complication when one wishes to discriminate between them.

   Another point for reflection in advance concerns integrating the quantitative ability of the measurement technique you intend to use with the quantitative characteristics of the populations you hope to discriminate between, or the effect size that you have determined you will need to achieve clinical relevance. For example, the smaller the differences are between expression levels of a biomarker that you wish to use to

discriminate between two populations, the more sensitive the quantitation method you choose needs to be. Consider the example of wishing to measure the treatment effect of drug *X* on a disease by assessing whether a biomarker is increased from disease-typical levels to the level seen in healthy persons. Would one be able to accomplish this with statistical confidence if the two populations showed close levels or overlap between their two distributions? If the difference between the populations is not big but the measurement error margin is, one may be doomed to an incapacity of discerning what one hopes to, regardless of the potential effects of the treatment. In this case it is wiser to rethink the fundamental premises of your study design and methodology before starting. Although this may sound like an obvious point, when one considers the common practice of ignoring measurement error and ignoring the compound error introduced by common study practices such as normalizing one assay result to another, it should perhaps give pause for thought.

3. Is your design sufficiently powered to detect what you wish to detect? Statistical power is the ability of a study to enable detection of a statistically significant difference when there truly is one; power in the statistical sense is analogous to the sensitivity of a diagnostic test [24]. Eng says: "One could argue that it is as wasteful and inappropriate to conduct a study with inadequate power as it is to obtain a diagnostic test of insufficient sensitivity to rule out a disease" [25]. In clinical trials, power often receives attention, perhaps thanks to ethics committees that have pointed out that it is frankly unethical to expose people to the risks and discomforts of research if the study has no potential for scientific gain, such as if a study was not designed to include enough people to adequately test the research hypothesis [26]. In laboratory experiments, on the other hand, statistical power is rarely estimated [1] and seems in general overlooked and poorly understood.

   To ensure sufficient power, one needs to think ahead and choose an appropriate sample size. Factors playing a role in how one would define *appropriate* include:

   a. The smallest meaningful difference between the two means being compared that the investigator would like the study to detect (this is usually based on subjective criteria such as judgment of clinical importance; additionally, sensitivity and error margins of the measurement method may influence its choice).
   b. The estimated standard deviation within each comparison group (this can be based on a pilot study, prior literature that has been carried out with the same outcome measure, or subjective criteria).
   c. The desired power level (this is usually 80% or higher; however, although high power is desirable, it is always in a trade-off with a fixed amount of time and resources for the study).

d. The significance criterion (usually set at 0.05).

e. Whether one- or two-tailed analysis is planned.

There are different formulas for computing power or sample size, depending on the experimental design and whether data are continuous or categorical; Example 3 shows an illustrative calculation using a formula suited to a standard design involving comparing means of two groups.

---

**Example 3.** You have qualified your biomarker $X$ as an efficacy marker in your disease model. In your studies qualifying $X$ as a biomarker and developing a method to assay it, you found that its expression was low in rats with your disease of interest (10 ± 3 units; mean ± SD) but higher in healthy rats (100 ± 30 units). You also noted that interventions that increased $X$ were associated with improvements in disease morbidity and that previous groups of animals studied tended to show biological variability of about 30% coefficient of variation between rats in a treatment group. You wish to design an appropriately powered study comparing untreated diseased rats to those treated with a single dose of your new treatment $Y$, to determine if $Y$ demonstrates efficacy, and have decided that a mean 5-unit change in $X$ is the lowest meaningful change that you wish to be able to detect. You will settle for standard levels of a significance level of 0.05 and a power of 80%. How many rats do you need in each group?

$$n \text{ of each group} = \frac{\left(\mathrm{SD1}^2 + \mathrm{SD2}^2\right)\left(z_{\mathrm{crit}} + z_{\mathrm{pwr}}\right)^2}{D^2}$$

where SD1 is the standard deviation of group 1 and SD2 that of group 2 to be compared to each other (for a minimum difference from 10 to 15 units, this would be 3 and 4.5, respectively); the $z$-values are standard normal deviates corresponding to selected significance criteria and statistical powers ($z_{\mathrm{crit}}$ for two-tailed $p < 0.05$ is 1.960, $z_{\mathrm{pwr}}$ for 0.80 power is 0.842; these and other values are found in standard statistical tables and software packages); and $D$ is the minimum difference that one wishes to detect (5 units).

$$\begin{aligned} n &= \frac{\left(3^2 + 4.5^2\right) \times (1.960 + 0.842)^2}{5^2} \\ &= \frac{29.25 \times 7.851}{25} \\ &= 9.2 \end{aligned}$$

Round up to 10 rats in each group.

---

Numerous Web page calculators and statistical programs are available to perform this type of calculation for you; however, it is difficult to use them properly without a working knowledge of the factors affecting power. This subject is well explained by Eng [25,26].

If your study is already complete and you found a significant difference, you do not have to be concerned as to whether the study was sufficiently powered. This is akin to wondering if you put enough dynamite under the bridge after you have blown it to smithereens. If, however, you found no significant difference and you are feeling uncomfortable about the fact that you did not consider calculating the power before starting the study, you may be tempted to do so after the fact, by plugging the values actually observed in your study for standard deviation and the difference between the populations into the power formula. This practice, dubbed *retrospective power analysis*, is problematic, because it does not tell you what the power to find the smallest meaningful difference was, only what the power was to find statistically significant the difference that actually existed between the groups in your analysis; furthermore, this "observed" power will be inversely related to the *p*-value observed, so it does not add meaningfully to the information already obtained with the *p* value [26]. Instead, approaches involving confidence intervals or chi-square tests are recommended to guide the interpretation of negative results [27]. Some practical considerations about power and sample size are discussed further on page 264.

4. Have you planned in advance which groups you are going to compare to which, for significant differences? Planned comparisons allow the researcher a greater rejection level $\alpha$ or *p*-value than do unplanned comparisons. This is because if you first look at your data, then choose your comparisons, you are introducing bias into your analysis, and the rejection level will have to be tightened to compensate for that [28]. Planning ahead also allows you clear-headed time to consider which comparisons you really need when your design includes many different groups. The more comparisons you make, the more the *p*-value will have to be adjusted against false positives, in effect making it harder for you to see a true positive. Therefore, it is important not to compare groups that are irrelevant to your experimental goals. This is discussed further on page 272 and in Example 6.

## Taking Care of Business

As touched upon previously, the challenges faced by industry-based scientists often include business-related considerations that are not considered in most statistics manuals. In particular, time and resource constraints are often significant, as well as pressures to proceed at a pace that is intended to satisfy management, investor, or profit-related concerns, but is often incompatible with sufficient depth of study or optimal experimental design. In short, between

the business and science aspects of the industry, a strong pressure front constantly flows from the business side to the science side.

At times when shortsightedness and lack of understanding of the impact of financial decisions on scientific practice threaten to nullify the potential uses of our scientific output, we should certainly consider exerting a pressure front in the opposite direction, from science to business. Since we cannot realistically hope to change the pressures of the business world, however, we need to at least consider modifying our experimental design and/or data interpretation approaches to take their effects into account.

For example, let us consider the case of a study design for analysis of a biomarker as a pharmacodynamic (PD) endpoint in a clinical trial,where each patient provides a pretreatment control sample to be compared with a time series of their posttreatment samples. Given an endpoint assay with a high between-experiment variance component, the wisest experimental design might be to study all of a given patient's posttreatment samples within the same assay, together with the matched pretreatment sample.

Instead, scientists are often pressured to run assays and provide PD results as soon as the first or first few of several posttreatment time point samples become available in clinical trials. This business-driven decision is often made despite freezer stability of samples, simply because drug development companies are anxious to get the news about their product's effects in clinical trial announced as quickly as possible; good news has an economic payoff, and similarly, the earlier that bad news is known, the better the chances for diverting precious resources before they are wasted. In the laboratory, however, the corollary of this pressure may be that precious volumes or tissue samples from a pretreatment control are used up in the first analysis, and later analyses on samples not yet collected will have to be calculated in assays that lack this internal per-patient control. As well as introducing bias between the time points that were assayed within a single run and those that incorporate between-assay variability, the added component of variability between assays may add unnecessary noise, obscuring potential treatment effects.

Certainly, as drug development scientists we cannot ignore concerns such as continued supply of cash by investors; indeed, such issues are supremely important to whether a scientific endeavor can even be continued. The point is that the effects of making less than ideal experimental design choices, too, should not be ignored or glossed over (which is, in fact, what tends to happen). Often, no consideration is given in the statistical analysis model to sample processing issues such as that described above, with raw values instead being logged into tables as if they had all been generated in a single assay of balanced design, regardless of the circumstances under which the data were generated.

Obviously, there is no one correct approach to remedy such a situation, and the researcher must decide what best fits the situation, hopefully with the help of a statistician who understands the sample processing issues. For instance, in some cases the best solution might be to convince decision makers to wait for a controlled comparison of pre- and posttreatment samples, in others it might

be including an internal standard for normalization and changing to a ratio-data design, yet others might be amenable to another analysis strategy. The point is that analysis and/or interpretation of the data should be rethought in the light of particular business decisions that have affected their generation.

In another example of rethinking assay design strategies to respond to the challenges of the business world, one might consider various strategies to increase statistical power in the face of time and resource constraints that typically limit the number of patients one can study. Browner et al. [29] and Eng [25] list a number of strategies for minimizing the sample size while maintaining power.

1. Use continuous measurements instead of categories; this is because, for a given sample size, statistical tests for continuous values are mathematically more powerful than those used for proportions.
2. Seek to decrease the variability of the measurement process (i.e., improve the precision of your processes, optimize your assays; the less standard deviation, the more power).
3. If possible, use paired measurements, matching each patient to his or her own control. Paired measurements are more powerful than unpaired measurements.
4. Add control subjects, even if case subjects are too difficult to obtain. Although it takes more complex equations to calculate power in unbalanced designs than if both groups have the same size, this will still add power.
5. Expand the minimum expected difference-perhaps that which you have specified is unnecessarily small and a larger expected difference could be justified, especially if the study is preliminary, or intended as a screening test. The smaller the expected difference you want to pick up, the greater the number of samples needed to give an equivalent power.
6. Reflect on whether your hypothesis could have merit as a one-tailed, rather than a two-tailed one (although in most cases this is not an option). You can obtain equivalent power using less samples for a one-tailed test. The sample size necessary for a one-tailed design with a 0.05 significance criterion is the same as that for a two-tailed design with 0.10 significance, if all other factors are equal.

Many researchers think of power calculations as a futile exercise, likely to specify an unrealistically high sample size, given the resources on hand for the study. In fact, proper thought to power and the factors that contribute to it could, in many instances, lead to cost and resource savings. Rather than applying an across-the-board animal toxicity experimental design including, for example, 10 animals per group, Example 4 shows a case where five animals per group would be sufficient; as this example is built on a data set similar to the one used in Example 3, which showed 10 animals per group as being

appropriate for the experimental paradigm, it also illustrates that the number of samples that need to be in a test group for appropriate power depends strongly on issues specific to each particular research question.

Thus, industry-based scientists grappling with business cases, profit-and-loss issues, how best to spread their research budget over the necessary items, and other financial-based decisions with an impact on scientific quality would do well to manage their resources appropriately by incorporating power calculations into the design of their laboratory research.

---

**Example 4.** Imagine an example similar to that described in Example 3, except that the biomarker is now a toxicity marker, which you have qualified and shown low under normal conditions in rats (10 ± 3 units; mean ± SD) but markedly increased in response to toxic reactions (10- to 100-fold). You wish to test a compound for toxicity using the same experimental design as in Example 3, but with a few different assumptions:

1. Because of being cautious about the risks of toxicity, you want to ensure higher than 80% power this time: You want to ensure 95% power, so you have more certainty that any finding of no significant difference in the toxicity marker would not be attributable to too few animals being studied.
2. Because you are not concerned if the toxicity marker decreases in association with the treatment, but only if it increases, you adopt a one-tailed design.
3. Because toxicity so markedly increases the biomarker, you decide that the smallest meaningful increase you wish to detect can be greater than in Example 3. You decide that 20 units of biomarker would be greater than 3SD over the normal condition and is thus an acceptable threshold, so you set $D$ at 20 − 10 = 10.

How many rats do you need in each group?

Using the same formula as in Example 3, but substituting a $z_{\text{pwr}}$ value of 1.645 (the value for 95% power), a $z_{\text{crit}}$ value of 1.645 (the one-tailed value for a $p < 0.05$ significance level), a $D$ value of 10, and SD1 and SD2 values of 3 and 6, respectively:

$$\begin{aligned} n &= \frac{(3^2+6^2)(1.645+1.645)^2}{10^2} \\ &= \frac{45\times 10.824}{100} \\ &= 4.87 \end{aligned}$$

Round up to 5 rats in each group.

---

## The Odd Risk

Biomarkers are often used in studies that involve nominal data, such as a positive/negative dichotomy for a test result. There are various ways of quantifying the strength of the relationship between groups when it comes to this type of data, which is sometimes also referred to as *proportional data*, in reference to the fact that one measurement is often expressed as relative (proportional) to another (i.e., a percentage of patients responding, or the accuracy or sensitivity of a diagnostic test). Proportional data is often presented in a $2 \times 2$ contingency table. The chi-squared statistic is appropriate to test the null hypothesis of independence between row and column variables. Data are often described, however, in terms of difference of proportions, relative risk, or odds ratio. These are not statistical terms, but rather, quantification terms. Often, these are misunderstood, sometime leading to serious confusion and misinterpretation of published research. When considering the use of diagnostic tests classifying disease states, based on biomarkers, the terminology of odds and risks is actually less useful than true and false positive and negative rates, since it does not capture the aspect of error in disease classification. It is nonetheless important to be able to interpret research correctly where results are described in odds/risks terminology. This subject is well explained in a review by Sistrom and Garvan [30], from which most of the following is paraphrased.

Assuming a data table comparing some outcome measure in two groups, one of which was exposed to some variable and the other of which was not, the difference in proportions is the proportion with the outcome in the exposed group minus the proportion with the outcome in the unexposed group. It is always between –1.0 and 1.0, and equals zero when the response $Y$ is completely independent of the explanatory variable $X$.

*Relative risk* is a measure of association between exposure to a factor and risk of a certain outcome, and is defined as risk in the exposed groups divided by risk in the unexposed groups. Public health impact depends not just on relative risk but also absolute risk, so just looking at relative risk can be misleading. For example, the public health impact of a vaccine that halves the risk of an infection is very different for a rare (say, two cases per million people) or a common disease (say two cases per 10 people); in both cases the relative risk for vaccinated subjects would be 0.5 compared to unvaccinated subjects, but in the former case, for every million people vaccinated, only one would be saved, whereas in the latter case it would be 100,000 people saved [31].

*Odds* are the probability that the outcome does occur divided by the probability that it does not occur, with the *odds ratio* being the ratio of the odds of an outcome in one group ("exposed") versus another ("unexposed"). A key concept about using odds to estimate risk of an event is that the relationship between the odds ratio and the risk ratio depends on the outcome frequency of the event. If the odds of an event are greater in one group than another, it does *not* mean that the risk ratio is increased by the same amount.

This is a very common misunderstanding, but in fact, odds ratios and risk ratios are similar only when the outcome being studied is rare (i.e., about 10% or less probability in the unexposed group) [32]. Odds ratios are not a good estimate of risk ratio when the outcome is common in the population being studied. In that case, to obtain correct risks one needs to apply the equation relating odds to risks, as shown in Example 5.

---

**Example 5.** The equation relating risk ratio (RR) to odds ratio (OR) is as follows:

$$\mathrm{RR} = \frac{\mathrm{OR}}{(1-\mathrm{Pr}_0)+(\mathrm{Pr}_0)(\mathrm{OR})}$$

where $\mathrm{Pr}_0$ is the probability of the outcome in the unexposed group. Schulman et al. [33] compared the frequency of referral for cardiac catheterization for white men (exposed) to that for black men (unexposed). Black men were referred 90% of the time, and the odds ratio for black to white men being referred was 0.6:1. The risk ratio for black men to white being referred was

$$\begin{aligned}\mathrm{RR} &= \frac{0.6}{(1-0.9)+(0.9\times 0.6)}\\ &= \frac{0.6}{0.64}\\ &= 0.94\end{aligned}$$

---

This example shows how an odds ratio of 0.6 for referral to cardiac catheterization for black men vs. white men (as reported by Schulman et al. [33]) does not mean that blacks were referred 40% less often than whites, as was reported in extensive media coverage following publication of that study. Once the correction for a 90% referral frequency for black men was applied, the risk ratio for black men to be referred was 0.94, or 6% less relative to white men rather than the 40% less that the media coverage of the original study had interpreted [34].

## PRACTI(STI)CAL MAGIC: WHICH WITCH IS WHICH?

During my time as a contract research organization scientist, I was astonished at the frequency of requests from pharmaceutical and biotechnology clients to perform inappropriate statistical treatment of the results; it seems that in the drug development industry at least, there is an appreciable level of confusion over when particular tests are appropriate and what underlying assumptions must be met for them to be valid. Accordingly, some refresher basic statistics background is summarized briefly below.

## Parametric vs. Nonparametric

Parametric tests are so named because they use parameters, such as mean and standard deviation, in their computations. Student's *t*-test and the analysis of variance (ANOVA) are examples of this type of test. Parametric tests assume that the data sets are normally distributed and that the various groups have roughly equivalent variance between members of the group. They are prone to falsely indicating a significant difference between the groups if these assumptions are not met. In that case, nonparametric tests provide an alternative. Nonparametric tests rely on ranking of samples relative to each other, and make fewer numerical assumptions. They are less likely to commit type I error, but usually also have less power to reveal true significant differences.

Researchers need to evaluate data with descriptive statistics in order to decide whether the assumptions of the more powerful parametric tests are met or whether nonparametric tests would be the more appropriate choice. Some assumptions apply to both types of test and must also be considered. In that regard, both parametric and nonparametric tests assume that samples included in the analysis are independent of each other. How does one judge whether these assumptions are met, and what should one do about it if they are not?

***Independence*** To judge whether samples are independent, one needs to ask if within any one group of data included in the analysis, the value of one data point is somehow related to another. If the answer is yes, these samples are not independent. For example, if biomarker expression is measured in two separate tissue samples three separate times each and you enter $n = 6$ data items into the analysis, you have violated the independence criterion. The three replicates of each sample are related to one another (from the same tissue sample); there are actually only two independent measures, not six. Since $n = 2$ is not enough samples to analyze statistically, potential plans to redress this analysis error could include either omitting statistical analysis in favor of descriptive results only, or redesigning the experiment to include additional tissue samples.

Often, experiments are designed to measure biomarker expression repeatedly in a single subject, such as in the case of pharmacodynamic measures at different time points following administration of a drug in clinical trial patients. In this case, the independence assumption is not violated, since the related measures will be analyzed as different groups rather than being included within one group. Repeated-measure statistical tests are then applicable, such as the paired *t*-test (for two measures) or repeated-measure ANOVA (for more than two measures).

To reiterate, then, if samples are not independent of one another and they do not constitute repeated measures, the correct statistical approach is to redesign your experiment. Although more complex analysis strategies do exist

for clustering correlated samples within groups, there is no manipulation when using simple tests of significance that will correct for samples in one data set being selected such that the choice of one sample depends on another sample being picked.

***Normally Distributed Data*** How do you judge if your data are normally distributed? The first step is to perform descriptive statistics and plot the data out as a histogram. In a normal distribution, about 68% of the data falls within 1 standard deviation (1 SD) of the mean, and 95% within 2 SD of the mean. Many statistics programs will compute normality for you using statistical tests. The Kolmogorov–Smirnoff test, for instance, has nothing to do with martinis, being instead one such test for the normal distribution of data. If you have around $n = 25$ or more in each group, you can safely apply the simple eyeball test to your data, accepting data as normal if points fall into a roughly bell-shaped curve when plotted as a histogram [35].

What if you are not sure whether your data are normally distributed? If you have small data sets, for instance, normality can be difficult to determine visually. Similarly, statistical tests do not have much power to make the determination in this case. At this point, one's own personal choice comes into play: If you are conservative, you might choose to play safe with a nonparametric test; if not, you might choose a parametric test. As with other life choices, there are risks associated with either: With parametric tests you risk error of type I, whereas with nonparametric ones you risk type II error. The best solution might be to collect reasonably large data sets so as to avoid this uncertainty.

Assuming you do have a large enough data set to be certain, and what you are certain of is that the data are not distributed normally, well, what then? One solution might be to transform data mathematically such that the transformed data sets become normally distributed, in which case the more powerful parametric tests can then be used. Some commonly used transformations and appropriate types of data for their use [35–38] are listed in Table 1. If data are still not normally distributed with equal variances following mathematical transformation, a nonparametric test should be chosen for analysis. Some appropriate nonparametric equivalents of parametric tests are shown in Table 2.

***Equivalent Variances Between Groups*** As with the question of whether data are normally distributed, equivalence of variance between groups needs to be evaluated prior to choosing appropriate tests of significance. Sometimes, homogeneity of variance from one group of data to another can be amply judged by plotting a frequency histogram of each group and seeing how spread out the data are, or calculating the variance for each group and qualitatively assessing if the numbers are very different or appear close. It is simple enough, however, to apply the appropriate statistical test, the $F$-test for two groups, or the $F_{max}$-test for more than two.

**TABLE 1 Common Data Transformations**

| Type of Data | Example | Transformation |
|---|---|---|
| Proportional data | 0–100% | Arcsin of the square-root transformation |
| Poisson distributed (counts of random events) | Number of cells of a particular type in a given volume of blood | Square-root transformation |
| Variance proportional to mean squared (i.e., standard deviation proportional to mean) | Serum cholesterol levels in patients | Log transformation |
| Ratio data (normalized to internal standard on a per-assay basis) | Blots normalized to a housekeeping gene | Log transformation |
| Highly variable quantities, where variance is proportional to the mean to the fourth power (i.e., standard deviation proportional to mean squared) | Serum creatinine levels in patients | Reciprocal transformation |

**TABLE 2 Nonparametric Equivalents of Parametric Tests**

| Parametric | Nonparametric |
|---|---|
| Student's *t*-test (unpaired) | Mann–Whitney test (Wilcoxon rank sum) |
| *t*-test (paired) | Wilcoxon signed-rank test |
| *t*-test (paired), in cases where data are not symmetrical around the median | Sign test |
| ANOVA (without repeated measures) | Kruskal–Wallis test |
| ANOVA (with repeated measures) | Friedman's test |

*Source:* Adapted from ref. 35.

If variances differ between groups and are not rendered equivalent by mathematical transformation (see Table 1), you may still be able to use parametric statistics. If, for example, the *t*-test is appropriate to your experimental design, and variances are unequal between groups but not extremely disparate, you may choose to use the *t*-test for unequal variances (in the case of extreme differences in variance, however, a nonparametric test is the recommended alternative).

If your intended parametric test is ANOVA, on the other hand, the assumption of equivalent variance between test groups is essential [35]. If variances are not equivalent and transformation also does not render them equivalent, you must test statistically using a nonparametric equivalent (see Table 2).

## Simple Regression and Correlation Analysis

At times there seems to be some confusion about simple linear regression vs. correlation analysis. This issue is well summed up in a review by Zou et al. [20], from which the following information is, for the most part, culled. The two are similar mathematically, but their purposes are different. Both relate to a function that describes the relationship between a given $X$ and $Y$; however, regression analysis generally focuses on the form of that relationship and correlation generally on the strength. Furthermore, regression focuses on evaluating the relative impact of a predictor variable on a particular (dependent) outcome, whereas correlation's purpose is to examine the strength and direction of the relationship between two random variables.

Correlation analysis commonly involves either the Pearson coefficient ($r$) or the Spearman coefficient ($r^2$), with the former reflecting proportional changes in one variable when the other is changed, and the latter using ranks and reflecting instead a monotonic relationship between two variables (i.e., whether one tends to take either a larger or a smaller value than the other, but not necessarily with a proportional change in one variable when the other one is changed). If data sets are skewed or contain outliers, the Spearman coefficient rather than the Pearson is the appropriate choice.

Interpretation of correlation coefficients is often rather qualitative, with the sign indicating the direction of the relationship (positive or negative). Values range from 0.0 (no correlation) to 1.0 (perfect correlation), with 0.5 generally being thought of as moderate, 0.8 as strong, and 0.2 as weak. Statistical significance can also be computed, by formulating a null hypothesis of no correlation and a one-sided alternative hypothesis that the underlying value exceeds or is less than that value, then computing the $z$-test statistic and rejecting the null hypothesis based on the $p$-value.

Simple linear regression analysis results in an $r^2$ value that is calculated on the basis of Pearson $r$ coefficient and reflects the fraction of the variability in $y$ that can be explained by the variability in $x$ through their linear relationship (or vice versa). As with correlation analysis, a finding of strong linear relationship in a regression analysis does not mean that the variable causes the outcome (as discussed in the section on misuses of correlation), and should not be interpreted that way. Student's $t$-test can be used, for example, to test if there is a linear relationship (i.e., null hypothesis of slope = 0) or whether the $y$-intercept is a particular value. As a salient point, no extrapolation outside the range of values of the independent variable in the regression analysis should be used to make any predictions.

## *t*-Test vs. ANOVA

Using inappropriate tests of significance for the circumstances, such as testing differences between more than two groups by means of repeated $t$-tests rather than by ANOVA, is exceedingly common [35]. Don't do it! Repeating

pairwise comparisons ignores the experimental effects in all but the two groups being compared and increases the number of false-positive "significant results" expected; multiple means comparisons following ANOVA correct for the increasing chances of false positives by adjusting the acceptable hypothesis rejection level.

If you have only two groups to compare to each other and they meet the assumptions of parametric tests, use Student's *t*-test. If you are testing more than two groups, however, use ANOVA. Since a standard ANOVA will tell you if there is a statistically significant difference somewhere in your data sets but will not tell you where, you need to apply a multiple means comparison test after the ANOVA, to pinpoint the culprits. There are many tests available, each suited to different types of data, so it is advised that you consult the help menu of your own statistical program to decipher which one best fits your own experimental design. As a rule of thumb, do not choose to make any more comparisons than are appropriate for the goals of the experiment, or you risk to lose the ability to detect significant differences that may truly exist. This is because multiple means comparison tests apply corrections that tighten the rejection level in proportion to an increased group comparison number (i.e., effectively lowering the *p*-value required to find a difference significant). In general, you can make one less comparison between groups than the total number of groups, without affecting this rejection level; however, if you exceed this, the rejection level is adjusted. Dunnett's test, for instance, is suited to designs such as a dose–response curve, which include a matched control sample and several different doses; this test compares each group only to the control (not to each other), to answer the question "Which dose(s) give(s) a response" but not "Was the response to one dose different than to another?" Example 6 shows how a significant difference between the control and treatment groups could be missed if more comparisons were made than necessary.

---

**Example 6.** You wish to test for whether any of several doses of your treatment has a significant effect on your outcome. You have collected samples *a*, *b*, *c*, *d*, (i.e., four groups), where *a* is the control and *b*, *c*, *d* represent responses to three different concentrations of your treatment. Assuming that your highest dose, *d*, shows a *p*-value of 0.02 with respect to control, this difference would be reported as significant by Dunnett's test; that is, three comparisons would be made (*b* vs. *a*, *c* vs. *a*, *d* vs. *a*), one less than the total number of groups, so no adjustment to the rejection level would be necessary to compensate for multiple comparisons, and the *d* vs. *a* calculated *p*-value of 0.02 ($\leq 0.05$) would be interpreted as statistically significant.

---

If instead of Dunnett's test, the Bonferroni test were chosen, six comparisons would be made (the same three as above, plus *b* vs. *c*, *b* vs. *d*, and *c* vs. *d*). Since this would be two more comparisons than the number of groups, the significance threshold of 0.05 would be adjusted to compensate for multiple

comparisons (0.05/6 = 0.008), such that a computed $p$-value of ≤0.008 would be required for significance at the so-called 0.05 rejection level (i.e., $p = 0.02$ would not be considered significant).

### One-Tailed vs. Two-Tailed

The tails referred to in your statistical package are the nonwagging variety; the term represents the tail edges of the bell-shaped normal distribution. Tests are one- or two-tailed depending on whether they compute the probability of values exceeding the range expected from members of a population in only one direction or potentially in both directions (i.e., greater than or less than).

Using a one-tailed test is justified only if there was an a priori determination that only differences in one specified direction would be assessed, not because one decides after seeing that the one-tailed $p$ is significant but the two-tailed is not, that one only really cares about one direction anyway. Furthermore, having an expectation that the difference to be found will go in a particular direction is not considered adequate justification for performing one-tailed analysis; rather, one-tailed analysis could be considered appropriate if having a large difference in one direction vs. having no difference at all would have equivalent consequences [39]. Under most circumstances a two-tailed test is the appropriate choice, and if the researcher is in any doubt about which is appropriate, the two-tailed should be chosen.

### Paired vs. Unpaired

Paired analysis is appropriate in the following circumstances:

- When you do a before and after measurement in each subject.
- When you match subjects in pairs (i.e., age, etc.), then treat one of the subjects and not the other. Pairs must be made before data are collected.
- When you compare relatives (i.e., sibling studies).
- When you perform an experiment many times, each time with the experimental and control sample treated in parallel (including log-transformed ratio data, as described in Example 7).

---

**Example 7.** You have done Northern blots of gene expression in mutant animals vs. wild-type animals. Each of your blots shows wildly different signal magnitudes from other blots, due to technical reasons such as exposure time; having mutant and wild-type samples on every blot allows you to control for this variability by expressing data as a ratio of mutant to wild-type values.

Ratios are not normally distributed, but logs of ratios are; therefore, you log-transform your data. Ratios become differences when log-transformed [i.e., log(mutant/wild type) = log(mutant) – log(wild type)], so to analyze this type of data you can take the log of each data point and perform a paired $t$-test on the transformed data.

---

In judging whether distributions are normal in paired testing, it is the differences between the two members of each pair that must be approximately normally distributed rather than the two distributions themselves. If data from two sets to be compared do not meet one of the criteria above, they should be analyzed by unpaired testing [35].

## Miscellaneous Data

***Outliers*** Within any set of observations it is not unusual to obtain occasional data points that vary substantially from others found in the same group of subjects. These *outlier data* may be the result of unknown errors or may represent genuine information, and indeed, whether such data should be included or rejected is the subject of much debate. Methods for detecting outlier data and the use of robust methods of statistical analysis to accommodate such data are complex issues, beyond the scope of this chapter; a thorough treatment of the subject is presented by Barnett and Lewis [40], to which the reader is referred.

***BLQ Data*** Statisticians sometimes warn against *left-censored distributions*, a term evocative of political intrigue and vaguely racy data sets that actually refers to the more bland reality of omitting results that are below the levels of quantitation of the assay (BLQ). BLQ results are fairly common in clinical and preclinical biomarker analyses and can cause serious problems with interpretation of the data if they are not taken into account, since unreported values are unusable in any statistical analysis of the data. Data imputation, a process to replace unreported BLQ values with valid estimates, can also affect the data interpretation, since all values in a data set affect the measures of central tendency, error, and statistical power. It seems clear that estimating a theoretical value for BLQ data points would allow for more accurate conclusions to be drawn from the data than simply removing data through left-censoring, but what value should indeed be assigned to BLQ data points?

Some researchers report BLQ values as zero, perhaps due to the influence of the sometimes black-and-white perspective of assay validation-style cutoffs. Assigning a zero value regardless of the sensitivity of a given test could be misleading, however, since zero is an absolute, whereas BLQ represents a scale from zero up to an upper limit that differs from one test to another in an assay-specific manner. Furthermore, assigning zero values creates other mathematical difficulties, such as not being able to compute fold-differences of another value with respect to the zero, or not being able to work with log transforms of data.

One common approach to address these issues in the data imputation process has been to assign arbitrary nonzero values to BLQ data, most commonly either the limit of detection (LOD) divided by 2 or divided by the square root of 2, depending on the skewness of the data set in question [41]. Both appreciable bias and loss of power have been demonstrated with this

type of approach, however [42,43]. Succop et al. compared the bias of alternative methods for imputing BLQ values and concluded that by imputing the values based on either median percentiles below the detection limit or based on predicting the BLQ value from an equation model fit to the noncensored data set, both produced a good correlation between predicted and reported low values. In their example data set, bias between the predicted and true values was only 2.9% this way, compared to 348% overestimation bias when LOD/2 was used to impute the BLQ values [44].

Standard curves of analytical assays typically provide an equation model fit that can be used to calculate values down to the zero level, but assay validation typically limits the data reported to levels that have met a cutoff level that is deemed to have accuracy and precision within proscribed acceptance limits (i.e., the lower limit of quantitation). The study above suggests that although equation-predicted values below the levels of quantitation of an assay may not meet acceptance criteria per se, they still represent more accurate estimations for BLQ data than either arbitrary imputation methods or left-censoring of data sets. Succop et al. recommended that analytical labs should provide a numerical result for all samples analyzed, with a flag of those values that are below the detection limit [44].

## ISSUES SPECIFIC TO SPECIALIZED FIELDS

### Genetic Association Studies

Genetic association studies evaluate the association between specific genetic polymorphisms and disease. They often assess relatively small effects against a noisy background of biological and social complexity, and consequently, tend to lack statistical power [45]. Power calculations are critical for genetics researchers who wish to map susceptibility genes, with chi-square being the most commonly used test statistic for association studies. The noncentrality parameter for the chi-square asymptotic distribution developed by Mitra [46] is the key to computing power and sample size for this type of study. Gordon and Finch present detailed instructions (including step-by-step use of a Web-based calculator) for this, as well as reviewing other concepts of statistical genetics and the best study/analysis design to optimize power for this type of study [17].

Synthesizing evidence from multiple studies has been used as a means of increasing power; however, it seems that metaanalyses in this field have been fraught with serious flaws. As well as more general concerns, there are genetic issues particular to molecular association studies, including checking Hardy–Weinberg equilibrium (HWE, discussed below), handling data from more than two groups while avoiding multiple comparisons, and pooling data in a way that is sensitive to genetic models [47]. As regards the latter two points, there are always at least three possible genotypes to compare, but in practice

most studies reduce the number of comparisons by assuming a specific genetic model, such as dominant or recessive, even though there are often no biological justifications for assumption of the model. Using an inappropriate genetic model or inappropriately pooled data produce misleading estimates of odds ratios. Appropriate metaanalysis methods and avoiding assumptions about genetic models are discussed further by Minelli et al. [45] and Thakkinstian et al. [48].

Bias seems to be another serious problem in this type of study. Some methods for detecting and correcting it are discussed by Sterne et al. [49]; publication bias, for example, may be detected by a simple funnel plot of the data. Not just the metaanalyses, but also single studies in this field seem excessively prone to various sources of bias, with some critics going so far as to assert that most documented associations, even those that are replicated, represent nothing other than false positives based on bias [50]. The list of prevalent bias sources is impressive and includes biological plausibility bias, ascertainment bias, publication bias, selective reporting bias, spectrum of disease bias, population stratification, biased selection of controls, lack of blinding in the genotyping process, and genotyping error.

Some of these error sources can be addressed simply through researchers being cognizant of them and striving to avoid them. For example, one can choose to blind genotyping rather than failing to do so. In another example, ascertainment bias can be avoided by scrutinizing controls with the same intensity as cases; this type of bias relates to the situation where affected individuals ("cases") have their DNA resequenced to identify rare variants. Identification of such rare variants in an affected group does not necessarily signify a role in disease (as is often assumed when only cases are ascertained by resequencing) since sequencing DNA from any group tends to turn up a few rare mutations. Instead, a strong and statistically convincing *preferential* presence of variants in the cases compared to controls (that had been scrutinized in the same manner) would support the involvement of the variants in disease [51].

In cases where being cognizant of the potential for bias does not allow us to avoid it, designing experiments and/or data analysis with an expectation of inevitable bias can dampen its influence. For example, designing studies to have higher than desired power can combat the power loss expected from genotyping misclassification errors, as discussed earlier. As another example, various statistical techniques that are robust to bias can be used, such as genomic control techniques or family-based methods to address problems of population stratification [17]. *Population stratification* refers to the situation in case–control studies where control groups are not well matched to case groups and in fact have different typical levels of what is being measured simply because they are from different populations. In this situation, association tests like chi-square may falsely indicate associations, even with as high as 100% probability.

In fact, having appropriate control groups is a key determinant of the validity of genetics association studies, and determining whether controls deviate from HWE is a standard way of evaluating this. Theoretically, disease-free control groups from outbred populations should follow HWE, as should combined cases and controls if they both have a particular disease (i.e., such as in studies where different treatments are evaluated). If they do not, it is a signal of some peculiarity, error, or problem with the data sets that could invalidate the key inferences from a genetic association study [52]. For example, if there is a recessive model and the control group has an excess or deficit of one group of homozygotes, this will directly affect calculation of the odds ratio (the control homozygotes divided by the other genotypes is the denominator of the odds ratio). Overall, if there is a significant deviation from HWE it should induce some thinking about the study; deviations could result from genotyping errors but may also arise from other sources. For example, HWE deviation may suggest that allele-based estimates of genetic effects are biased, or may give further insight into the population from which the data are derived.

A recent review of studies published in high-quality specialized genetics journals demonstrated that HWE is very commonly tested improperly or inadequately [3]. Of 776 associations tested, only 29% reported on HWE, introducing uncertainty as to if it was tested in the others. Furthermore, where HWE testing was described, the test was applied to the correct control group in only 50% of the associations tested. It is a common error to include the disease cases with the control cases in the HWE test when controls are disease-free. Combined cases and controls should be tested only when the controls have the same disease as the cases; otherwise, only controls should be tested. These authors recalculated HWE for the studies reviewed and noted that in most of the samples where HWE was actually violated, this was either not mentioned in the original article or HWE conformity was actually claimed.

Another common problem in the studies reviewed was the unjustified use of an inappropriate test. A number of different statistical tests could be used to test HWE (including chi-square, exact tests, and Bayesian methods), all based on the conditional probability that there would be the number of homozygotes that actually turned out to be in the sample. The chi-square test was the only test applied to HWE calculation in the studies reviewed, despite the fact that the chi-square asymptotic distribution is inadequate to deal with low genotype frequencies and is therefore not justified in studies involving them; in this case an exact test provides a simple and superior alternative [3,54].

A final serious concern in the studies reviewed was that only 7% of the studies had an acceptable power to detect HWE deviation, with most studies being much too underpowered to make any claim of lack of deviations. Whereas power to detect HWE is of secondary importance compared to the prime consideration of power to detect a genetic association, undetected modest HWE deviations could affect considerably the inferences of many genetic association studies [3].

## Microarray or Other "Omics"-Type Data

Relating "omics"-style biomarker data (gene/protein arrays, multiple *m*/*z* peaks from mass spectrometry, etc.) to clinical outcomes is the focus of a large body of research. Making statistically based decisions about what is expressed or produced differentially, and how this relates to outcomes is not simple for these types of studies. For one, the data are highly dimensional, with the number of variables often exceeding the number of samples by magnitudes (i.e., in contrast to the desirable format for statistical comparisons of a group of sufficient numbers of samples for each variable tested). Furthermore, data tend to be very "noisy," with widely different magnitudes of signals and the potential for large irrelevant signals to obscure lesser (but relevant) ones. This translates into an inherent tendency for algorithms fit to the data to be more influenced by noise than by salient interest points (a phenomenon known as *overfitting the noise*).

A recent review of analysis of genomics/proteomics data outlines the steps of quality control, clustering, classification, feature ranking, and validation [55]. In Joe/Josephine terms these could be described as checking and normalizing the data, grouping like things together, statistically evaluating their likely involvement with the outcome, getting rid of the dead wood, and checking the conclusions on an independent data set.

In the first stage, quality control and normalization of signals reduce the technical variability and ensure that biomarkers discovered are statistically significant. Cui and Churchill reviewed statistical tests that have been specifically adapted to cDNA microarray data analysis [56]; many of the issues discussed are similar for highly dimensional data from other study types. They conclude that fold-change is the simplest method for detecting differential expression of genes, but the arbitrary nature of assigned cutoff values, the lack of statistical confidence measures, and the potential for biased conclusions all detract from its appeal. They also stress the need to normalize data properly, such as by using intensity-specific thresholds, since otherwise an excess of low-intensity genes may be identified as being expressed differentially simply because their fold-changes have larger variance than the fold-change values of high-intensity genes.

Expression analysis steps following this generally fall into two categories, supervised or unsupervised, based on whether or not they are led by prior knowledge. Clustering is an *unsupervised method* that groups genes of similar expression profile together; clustered genes may have diverse biological functions, but this is nonetheless useful for exploring new territory and seeing who is dancing together. *Supervised classification methods*, on the other hand, train a mathematical model using prior biological knowledge of certain genes' functional involvement with each other, then use the model for predictions on other genes. This is a useful approach for building on what is already known, but in cases of limited available information it is difficult for a supervised method to achieve accurate predictions.

Flawed statistical analysis is very common in this emerging field, even in studies published in high-impact factor journals. Dupuy and Simon recently found that half of a survey of 90 microarray studies had at least one of three major analysis flaws [2]. (These authors also present a list of analysis do's and don'ts specific to this study type, to which the reader is referred for more detail.) Analysis flaws like those discussed in this review and elsewhere [53,57] can lead to completely erroneous conclusions about the utility of given biomarkers or "signatures" of multiple biomarkers as prognostic or diagnostic tools, and may underlie some of the problems reproducing data in this field.

One of the most common flaws present in the published studies was to perform multiple comparisons without making adequate adjustment for the expected increased false-positive rate. Although the standard of setting $p$ at less than or equal to 0.05 is accepted as a reasonable compromise between type I and II errors when data sets are relatively small, in the relatively large-omic data sets a $p$-value this high is not sufficiently stringent to identify disease screening markers with an acceptably low false-positive rate. For example, a microarray containing 5000 genes examined for meaningful relationships between the genes and some outcome using this $p$-value could be expected to yield 250 false-positive relationships due simply to chance.

Dupuy and Simon suggest that the simplest method to combat this type of error is to use a $p$-value of less than or equal to 0.001, which would give one false positive for every 1000 genes tested. Several other accepted methods are grouped under the term *family-wise error-rate control* (FWER), but they have been criticized for decreasing power substantially [58]; the Bonferroni correction (dividing the nominal significance level by the number of tests) is the simplest of these. The false detection rate (FDR) test (or Benjamini–Hochberg test) is a favored control statistic for microarray analysis and is included in statistical analysis packages such as SAM (statistical analysis for microarray). The FDR achieves the same control of false significant results while greatly improving the statistical power compared to FWER methods [59,60]. An FDR of 5% is not the same as a $p$-value of 0.05: $p = 0.05$ means that 5% of tested genes will be false positive, whereas 5% FDR means that 5% of positive genes detected will be false. For example, given a scenario of 5000 genes tested, with 20 of them being found positive, a $p$-value of 0.05 means that there could have been 250 false positives (due to chance alone), whereas an FDR of 0.05 means that only one false positive was attributable to chance alone.

A second common flaw was to make spurious claims of a meaningful correlation between clusters of genes and clinical outcome, when, in fact, correlation was detected after clustering using a selection of outcome-related differentially expressed genes. Therefore, genes being related to the outcome was a consequence of the selection bias, but was instead reported as independent proof of a correlation between the clinical outcomes and the gene clusters. A number of classification methods decrease noise in the data by requiring selection of the relevant and informative predictor variables before modeling

is performed [61], so users need to be aware that if they have used one of these methods there is no point in performing correlation analysis afterward.

The third major flaw concerned the mechanics of classification model validation. Once a model is constructed it is generally validated using either an external test set or cross-validation, with the end goal being to use the validated model to predict outcomes for unknown samples. In the studies reporting supervised prediction, Dupuy and Simon noted the common flaw of biased, overly optimistic estimation of the prediction accuracy through an incorrect cross-validation procedure. Different errors in cross-validation procedure were noted, but generally they were all related to failing to have test sets (data used to test the model's predictive capacity) completely uninvolved in generating the algorithm in the first place.

## Bayesian Information Integration for Personalized Medicine

A key challenge for the success of pharmacogenomics lays in defining analytical methods to integrate and interpret the increasingly complex information that it provides, so that decisions can be made about how people can best benefit from certain therapeutic interventions. Bayesian statistics approaches, often favored by decision theorists, have proven useful in classification models that integrate traditional clinical risk factors with complex genomics data. The point of doing this is to try to predict the outcome of future patients who share certain key clinicogenomic attributes with those from whom the model was derived and to use these predictions for patient-customized diagnostic, prognostic, and treatment purposes.

Most of this chapter is based on the classical frequentist approach to inferential statistics with which most of us are familiar. In this approach, a single hypothesis (the null hypothesis) is formed about the effect of (or, rather, lack thereof) a variable or several variables that are tested using a fairly rigid and well-defined format. The evidence against the hypothesis is all that is considered, and it is in the form of probabilities computed from the distribution of the outcome measure(s). A baseline assumption of randomness is assumed in defining what the probabilities are, and rejection of a null hypothesis is founded on the experimental result being too different from the random probability function to actually be random (i.e., therefore it isn't).

Bayesian statistics, on the other hand, represent a fundamentally different way of thinking about probability, with statistical inferences being made using accumulated evidence of all kinds, both for and against a hypothesis, or several alternative hypotheses. These hypotheses do not even have to be testable, let alone be tested, and certainly not by any particular format. (The name of the first publication of Bayes himself shows an example of such a hypothesis: Divine Benevolance, or an Attempt to Prove that the Principal End of Divine Providence and Government Is the Happiness of His Creatures [62].) Importantly, there is no baseline assumption of randomness: Instead, a "prior probability" is included in the paradigm. Although assigning it a value based

on random chances is one option, another is that prior knowledge is incorporated into this value; in this way, Bayesian methods build on past experience to make statistical inferences.

To compute the probability of each particular hypothesis being true, a calculation using Bayes' theorem would multiply all the conditional probabilities that each is true by their prior probabilities and weight the final values relative to each other. *Conditional probabilities* are those from each piece of evidence for or against the hypothesis, and *prior probability* is defined in a very open-ended way; it could be pretty much anything, including subjective feelings, provided that it is decided upon in a consistent manner between all the hypotheses, it sums to 1 for all the hypotheses, and the information used to produce it is not used again later as evidence. As more evidence accumulates, it can be incorporated into updated models [63]. A simple Bayes calculation has already been shown (see Example 2); in that case, known disease frequency in the population constituted the prior probability, and the predictive values of the diagnostic test for true and false positives were the conditional probabilities.

Biomarker researchers aiming to define predictive models for personalized medicine have showed how Bayesian methods can strengthen these models by integrating different types of information into them. For instance, Qi et al. noted that both supervised and unsupervised methods have different drawbacks for genomics data analysis, with the latter capturing relevant expression profiles but ignoring important a priori knowledge, and the former being limited where little prior knowledge exists. Accordingly, they used a Bayesian approach to perform accurate predictions even when scant prior knowledge is available; their integrated model achieved higher sensitivity and specificity compared to both unsupervised and supervised methods [64].

Similarly, Pittman et al. [65] used Bayesian tree modeling to integrate both clinical information and genomic biomarker status for a sample set of breast cancer patients. They showed that the integrated clinicogenomic model gave substantially greater log-model likelihood (>7) than the model based on genomic biomarker signatures alone, and blew the clinical predictors alone right out of the picture, with a weight of evidence for the clinicogenomic vs. the clinical predictors only of more than 26 log-likelihood units.

Tree models in general involve successive splitting of a given patient sample group with certain known characteristics (i.e., gene signature, clinical risk factors) and outcomes (e.g., cancer status, survival, relapse) into more and more homogeneous subgroups. At each split, the collection of evidence (e.g., clinical or gene factors) is sampled to determine which of them optimally divide the patients according to their outcome, and a split is made if significance exceeds a certain level. Multiple possible splits generate "forests" of possible trees.

Some caveats noted for those using these methods include how to choose among alternative potential models that are identified as being of similar or significant probability, and the issue of uncertainty. In that regard, whereas in

some other applications Bayesian approaches are used to choose a single best hypothesis from among several, such an approach is warned against for pharmacogenomic modeling applications [61,65,66]. In this case it is typical to see multiple plausible tree models representing the data adequately, and this is consistent with the physical reality of multiple plausible combinations of genetic and clinical factors that could lead to the same outcome measures.

Rather than choosing one of them, it is critical to define overall predictions by averaging across the multiple candidate models using appropriate weights that reflect the relative fits of the trees to the data observed. The impact of averaging is seen in greater accuracy of the model predictive capacity and, importantly, in accurate estimation of the uncertainty about the resulting prediction uncertainty (i.e., the prediction uncertainty of such a model is conceptually akin to the measurement uncertainty associated with a laboratory method, as discussed earlier). Nevins et al. underlined well the importance of prediction uncertainty when they pointed out: "A further critical aspect of prognosis is the need to provide honest assessments of the uncertainty associated with any prediction. A predicted 70% recurrence probability, for example, should be treated quite differently by clinical decision makers if its associated uncertainty is ±30% than if it were ±2% …" [66].

## SUMMARY: QUICK DO'S AND DON'TS

The field of biomarkers is a wide one, with a huge diversity of potential applications, all of which may have different and complex statistical analysis issues. This chapter has undoubtedly missed many of these and glossed over others, but summarizing concisely what it has covered is still a challenge. Instead, I present below a distillation in the form of one-liners addressing some of the more critical points ("do") and more common misconceptions ("don't").

Do:

1. Put on Hercule Poirot's hat and use your judgment when considering analytical issues and your experimental situation.
2. Think ahead: Consider data analysis issues before settling on your experimental design (and long before having the data in hand).
3. Take the limitations of your techniques and experimental error into account in your interpretations.
4. Check that your design is powered appropriately to detect what you wish to detect.
5. Use appropriate tests (i.e., ANOVA when comparing means from more than two groups).
6. Use appropriate controls and check HWE in genetic association studies.
7. Make adequate adjustment for the elevated false-positive rates when dealing with-omics-style data.

8. Average over multiple plausible candidate models with appropriate weights (rather than choosing a single one), for best predictive accuracy and uncertainty estimations in pharmacogenomic applications of Bayesian modeling strategies.

Don't:

1. Use parametric tests if data do not meet the assumptions of these tests (such as being normally distributed).
2. Use repeated *t*-tests when comparing means from more than two groups in one experimental design.
3. Compare more groups than are relevant to the goals of your experiment when applying multiple means testing.
4. Use correlation analysis to infer cause and effect or to test agreement between different methods.
5. Simply equate the odds ratio and risk ratio without considering the outcome frequency.
6. Use data to test correlation to outcomes or as a test set for validation of algorithms if they were already involved with those earlier in the process of mathematical modeling of genomics data (i.e., selected based on outcomes in the former case, or involved in algorithm generation in the latter).

# QUALIFICATION OF SAFETY BIOMARKERS FOR APPLICATION TO EARLY DRUG DEVELOPMENT

William B. Mattes, Ph.D., DABT

Frank D. Sistare, Ph.D.
*Merck Research Laboratories, West Point, Pennsylvania*

## HISTORICAL BACKGROUND TO PRECLINICAL SAFETY ASSESSMENT

It is often forgotten that the first "blockbuster" drug, sulfanilamide, was discovered and developed in an era devoid of regulatory oversight and guided only by free-market forces. Domagk discovered the antibacterial properties of Prontosil in 1932, and with the subsequent discovery in 1935 that the active moiety was the off-patent and widely available substance sulfanilamide, a number of companies rushed to make preparations for sale to the public. This explosion of therapy options was unfettered by requirements for medicines to be tested for efficacy or safety, although preparations could receive the endorsement of the American Medical Association [1]. Thus, in 1937, when the S.E. Massengill Company of Bristol, Tennessee, sought to prepare a flavored syrup, it simply identified an appropriate excipient to dissolve the drug, prepared 240 gallons of the raspberry-tasting Elixir Sulfanilamide, and marketed it across the nation. Unfortunately, the excipient chosen was diethylene glycol, also used as an antifreeze. We now know this agent to be lethal to a

large number of species, causing acute kidney injury at relatively modest doses. Before Elixer Sulfanilamide was identified as the causative agent and pulled from pharmacies, 34 children and 71 adults died. A year later, Congress passed the 1938 Federal Food, Drug and Cosmetic Act, requiring pharmaceutical manufacturers to show product safety before distribution [1]. Thus, society transitioned from its former free-market approach to pharmaceutical development to one of safety testing (initially in animals), careful clinical trials, and government oversight.

Safety testing as it is practiced today owes most of its form to procedures developed by the U.S. Food and Drug Administration (FDA) for testing food [2]. As early as 1949, the publication of "Procedures for the Appraisal of the Toxicity of Chemicals in Foods" began to formalize the practices the agency expected industry to follow in safety testing [3]. These practices included standard study designs and expectations as to what experimental observations would be recorded. They have evolved into the descriptive toxicity tests well known to modern toxicology [4]. Key to the value of these tests is not only their experimental design in terms of dose, route of administration, and duration, but also the endpoints evaluated, going beyond the observations of overall animal behavior and health. Thus, a battery of clinical pathology tests examining urine, hematological parameters, and serum chemistry is commonly evaluated [5]. Importantly, a number of tissues from the animal are examined both macroscopically and microscopically after sacrifice, and this histopathological examination allows for the identification of unusual and subtle lesions and changes following compound treatment [6].

In the arena of pharmaceutical product development, these studies, carried out in at least two animal species, one rodent and one nonrodent, are used to assure the safety of human subjects exposed to experimental doses of novel compounds [7]. The types and durations of studies required to support safety in various types of clinical studies have been codified by the International Conference on Harmonisation (ICH) and described in their guidelines on nonclinical safety studies [8]. Even so, human subjects need to be monitored for "adverse events and/or laboratory abnormalities identified in the protocol as critical to safety evaluations" [9].

## LIMITATIONS FACED IN PRECLINICAL SAFETY ASSESSMENT

A critical problem faced by nonclinical safety assessment groups in pharmaceutical drug development is the disparity of responses sometimes seen between the two nonclinical test species in the tools used to assess these responses. Historically, microscopic histopathology is used as a primary tool for identifying compound-induced damage. When damage is identified only at exposures far exceeding those expected in clinical studies, clinical safety is expected. However, microscopic histopathology is not a tool generally applicable to human studies, where clinical pathology measurements play the criti-

cal role in assessing adverse responses to drugs. Thus, if damage is observed in one nonclinical species at exposures close to those anticipated for human studies, the crucial question is whether the onset and reversibility of such damage could be monitored with clinical pathology or some other relatively noninvasive technology. Unfortunately, as described here, there are several types of drug-induced organ injury where current clinical pathology assays do not detect damage with sufficient certainty at early stages, and where assurances are needed that discontinuation of drug treatment would be followed by a complete and swift return to normal structure and function.

## Kidney Injury

Kidney injury may be produced by a variety of insults, including those induced by drugs or toxicants [10]. Given the known morbidity and mortality associated with acute kidney injury [11,12], evidence of drug-induced kidney injury in preclinical studies is a matter of serious concern. While on one hand the kidney is capable of recovery from mild damage [13] if the injurious agent is removed, the very real clinical problem is that traditional noninvasive measures of kidney function are insensitive and confounded by many factors [13–16]. Thus, even modest increases in serum creatinine are associated with significant mortality [12]. There is a real need for noninvasive markers that would detect kidney damage or loss of function at a stage before significant and irreversible damage has occurred. Several markers with just such a potential have been described in numerous reviews [13–20]. However, many of these are described in relatively few clinical studies, most have not been examined carefully for their performance in animal models of drug-induced kidney injury, and no consensus understanding between drug development sponsors and regulatory review authorities had been reached as to their utility for regulatory decision-making purposes. Ultimately, if a microscopic histopathological examination shows evidence of even mild drug-induced kidney injury in a preclinical study at exposures close to those anticipated for clinical use, development of that compound may be stopped, even if human relevance may be questioned, yet unproven.

## Liver Injury

The fact that medicines can cause liver injury and failure has been appreciated for some time [21], and drug-induced liver injury remains a serious public health and drug development concern [22–25]. As with other drug-induced organ damage, it may be detected in preclinical studies through microscopic histopathology and clinical chemistry measurements. Since the late 1950s, serum transaminase measurements, in particular that of alanine aminotransferase (ALT), have served as a sensitive and less-invasive measure of liver damage in both animal and human settings [26]. In conjunction with serum

cholesterol, bilirubin, alkaline phosphatase, and other factors, ALT has served as a translational biomarker for drug-induced liver injury [27–30]. However, ALT elevations are not always associated with clear evidence of liver injury [31–33], and ALT elevations cannot clearly indicate the etiology of damage [26,27,30,34]. Furthermore, ALT measurements either alone or with bilirubin cannot distinguish patients on a trajectory to severe liver disease and inability to heal or recover from injury, from patients with a full capacity to compensate and return ALT levels to normal despite continuation of drug dosing [35]. Combinations of clinical pathology changes have been used, including ALT and bilirubin, to assure safety in clinical trials [36] but there remains a need for diagnostic assays that reliably link and/or predict the histological observation of liver injury in both a preclinical and clinical setting, and discriminate the types and trajectory of apparent injury [30].

## Vascular Injury

Although injury to the vascular system is known to be caused by a variety of agents [37], many classes of therapeutic agents produce vascular lesions, in preclinical species with or without clinical signs, and with normal routine clinical pathology data [38]. Often, different preclinical species show a different level and type of response, and in many cases (e.g., minoxidil) the vascular injury reported in preclinical species is not observed in a clinical setting [39]. Drug-induced vascular injury in animals may result from altered hemodynamic forces, from a direct chemical-mediated injury to cells of the vasculature, and/or to an indirect immune-mediated injury of the endothelium and/or medial smooth muscle. The conundrum faced in drug development is that there are no specific and sensitive biomarkers of endothelial and/or vascular smooth muscle injury that are clearly linked to the histological observations in animals and could be used to monitor for injury in clinical settings. Although it is assumed that an inflammatory component may be active at some stage in this process, and biomarkers are proposed for such processes [40], biomarkers that are sufficiently sensitive at early and fully reversible stages of vascular injury have not been fully evaluated [38,41]. Furthermore, specific markers of vascular injury/inflammation are sought that can discriminate from the multitude of other more benign causes for elevations of inflammatory biomarkers.

## Drug-Induced Skeletal Myopathy

With the introduction of hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins), not only was there a successful treatment of hypercholesterolemia and dyslipidemia, but soon also a heightened awareness of the issue of drug-induced myopathy [42]. Statin-induced myotoxicity ranges from mild myopathy to serious and sometimes fatal rhabdomyolysis. Not surprisingly, a variety of drugs have been reported to induce myotoxicities

[43]. While skeletal muscle toxicity may be monitored with elevations in serum creatinine kinase (CK), urinary myoglobin, and other markers [42], these biomarkers lack the sensitivity to definitively diagnose early damage or to distinguish the various etiologies of the muscle injury [43]. Thus, there is a need for markers of drug-induced muscle injury with improved sensitivity, specificity, and general utility.

## WHY QUALIFY BIOMARKERS?

More often than not, new biomarkers are judged on the basis of whether they have been subjected to a process of validation. Strictly speaking, *validation* is a process to "establish, or illustrate the worthiness or legitimacy of something" [44]. For judgments of biomarker worthiness or legitimacy, an assessment is needed of both (1) the assay or analytical method to measure the biomarker, and (2) the performance against expectations of the biomarker response under a variety of biological or clinical testing conditions. The term *validation* reasonably applies to the first of these, the process by which the technical characteristics of an assay of a biomarker are defined and determined to be appropriate for the desired measurements [45]. Thus, Wagner has defined validation as the "fit-for-purpose process of assessing the assay and its measurement performance characteristics, determining the range of conditions under which the assay will give reproducible and accurate data" [46]. Even for assay validation, the concept of fit-for-purpose is introduced, which connotes that the process depends on context, and its level of rigor depends on the application of and purpose for the assay. Thus, a biomarker used for an exploratory purpose may not require the more rigorous analytical validation required of a biomarker used for critical decision making. The elements of biomarker assay validation that would be addressed for different categories of biomarker data and for different purposes have been discussed in this book and elsewhere, and they essentially constitute a continuum of bioanalytical method validation [45,47]. Such technical bioanalytical assay method validation is a familiar process and does not generally pose a problem for an organization embarked on assay development [45].

The term *validation* has also been applied to a process by which a new test method is confirmed to be broadly applicable to interpretation of biological meaning in a wide variety of contexts and uses, such as in the validation of alternatives to animal tests as overseen by the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) [48]. This process involving assessment of biological performance expectations is in contrast to that of *qualification*, which Wagner defines as "the fit-for-purpose evidentiary process of linking a biomarker with biological processes and clinical endpoints" [46]. As for assay validation, this fit-for-purpose biological qualification concept marries the nature and extent of testing rigor to the intended application. In the case of biomarkers applied to predicting human

outcomes, four general phases have been proposed [49], and as the level of qualification progresses, the utility of a biomarker in clinical use increases [46].

In the case of biomarkers of safety (i.e., those that are used to predict or diagnose adverse responses to drug treatment), this qualification process will necessarily involve certain steps. As with qualification of a clinical disease or outcome marker, these steps link biomarker results with biological processes and endpoints. For example, in qualifying a biomarker for nonclinical use, the levels of a protein biomarker in urine may be correlated with certain chemically induced microscopic histopathology lesions in the kidneys of treated animals and thus serve as a noninvasive diagnostic of the appearance of that lesion. As with a clinical disease or outcome marker, qualification of such a marker could proceed in stages. For the example given, an initial stage may be the correlation described, using a variety of treatments that produce only that lesion measured. Such a correlation could establish the sensitivity of the biomarker. However, establishing the specificity of that biomarker for that particular lesion would require a number of treatments that did not produce the lesion being monitored, but instead produce no lesions in the kidney or anywhere else, produced different lesions in the kidney, and/or produced lesions in different organs. Furthermore, the diversity of chemical treatments (i.e., structural and mechanistic diversity) would also need to be considered in the qualification such that a variety of mechanisms underlying the genesis and progression of the lesion can be evaluated.

Clearly, more data could support a higher level of qualification and thus a higher level of utility. For biomarker qualification, the highest phase or level of qualification is the status *surrogate endpoint*, in which case the biomarker can, in fact, substitute for and serve as the new standard clinical endpoint of how a patient feels, functions, or will survive: for example, in efficacy determinations to support marketing approval decisions. Qualified biomarkers that fall short as surrogate endpoints are nevertheless extremely valuable for both drug development and the general practice of medicine. The key to appreciating the value that will come from opportunities to deploy such biomarkers appropriately is in revealing a thorough understanding of their inherent strengths and limitations. In the early steps of designing studies to test sensitivity and specificity aspects of a biomarker's performance to reveal that thorough understanding, the strategy may be relatively clear. For safety biomarker qualification, the first and most important attributes to benchmark are knowledge of the biomarker link to biology and outcome, sufficient test sensitivity, and minimizing false test negatives. Evaluating the response of a new proposed biomarker in animals against biomarkers in conventional use using an agreed-upon set of well-recognized toxicants known to induce the desired organ injury is a fairly straightforward strategy. Pivotal, however, to the successful execution of such studies is to provoke a sufficient number of cases where the timing of the samples taken and the choice of dose levels will yield subtle and mild treatment-related effects at the boundary between normal and abnormal. A full spectrum of histologic treatment-related lesions from very

slight, to slight, mild, moderate, marked, and severe will be important in this regard for evaluating biomarker sensitivity.

The approaches taken for qualification of a safety biomarker for clinical uses will necessarily be different from those taken for nonclinical uses. Clearly, one cannot expect to have studies with healthy subjects intentionally exposed to a variety of toxicants, nor can one regularly use microscopic histopathology as a benchmark for clinical toxicity. Nonetheless, the goal is to reproducibly link the biomarker to a clinical outcome currently recognized and widely accepted as adverse. For certain types of drug-induced injury, there are standard-of-care treatments that unfortunately are associated with a known incidence of drug-induced injury. As an example, aminoglycoside antibiotic treatment is associated with a significant incidence of nephrotoxicity [50], mirroring the effects seen in animal models. Similarly, isoniazid treatment has a known risk of hepatotoxicity [51]. Thus, one approach to safety biomarker qualification in the clinic is to monitor novel biomarker levels longitudinally over the course of such a treatment and compare these with the current gold standard commonly used clinical biomarkers and outcomes [52]. Of course, one can complement these studies with those examining biomarker levels in patients with organ injury of a disease etiology [53].

The number of known agents appropriate for testing the sensitivity of safety biomarkers for certain target organ toxicities may be limited. It is generally expected that the number of studies conducted to evaluate sensitivity should reasonably represent a high percentage of the known but limited diverse mechanisms available for testing in animal and human studies. If the mechanisms are varied for each test agent and sensitivity performance remains high, the biomarker will probably find strong use potential. Specificity tests then become very important considerations in a qualification strategy. The number of test compounds that could be deployed to assess the false-positive test rate is far more expansive than the number of known compounds for testing sensitivity. Specificity testing therefore becomes a highly individualized dimension to a biomarker biological qualification strategy for biomarkers that pass tests of sensitivity. The two critical questions to address are whether (1) there are alternative tissue sources to account for alterations in test safety biomarker levels, and (2) whether there are benign, nontoxicologic mechanisms to account for alterations in test biomarker levels. To evaluate specificity, therefore, a prioritized experimental approach should be taken using logical reasoning to avoid the testing burdens of an endless number of possible studies.

The ultimate goal of these studies is the qualification to the level of what Wagner et al. define as a *characterization biomarker* [49], a biomarker "associated with adequate preclinical sensitivity and specificity and reproducibly linked clinical outcomes in more than one prospective clinical study in humans." Such a level of qualification then supports the regulatory use of these biomarkers for safety monitoring in early clinical studies with a new pharmaceutical candidate. A strong case has been made that for safety biomarkers for regulatory decision-making purposes, where the rigor of

supporting evidence would be expected to be high, that only fully qualified or "characterization" biomarkers are appropriate, and that there is really no regulatory decision-making role for exploratory and "emerging" or "probable valid" biomarkers. In this regard, measurements of such unqualified biomarkers in animal studies used to support the safe conduct of clinical trials would not be expected to contribute unambiguously and sufficiently to study interpretation, should not require submission to regulatory authorities, and therefore the exploration of their utility in such highly regulated studies should be encouraged [54] in order to accelerate the pace of biomarker evaluations and understanding.

## COLLABORATION IN BIOMARKER QUALIFICATION

Clearly, the number of preclinical and clinical studies and resources required to qualify a biomarker as a characterization biomarker appropriate for regulatory decision making are significant. Thus, it is no surprise that in their Critical Path Opportunities List the FDA called for "collaborations among sponsors to share what is known about existing safety assays" [55]. Collaborations of this type have indeed played key roles in addressing technological problems common to a competitive industry. Thus, Sematech, a consortium formed in 1987 and made up of 14 leading U.S. semiconductor producers, addressed common issues in semiconductor manufacture and increased research and development (R&D) efficiency by avoiding duplicative research [56]. Sematech demonstrates that consortia can provide an opportunity for industry scientists to pool their expertise and experience to confront mutual questions collectively. The International Life Sciences Institute has for several years served as a forum for collaborative efforts between industry and academia [57], and for the past six years a Biomarkers Technical Committee has been pursuing assay development and evaluation of biomarkers of nephrotoxicity and cardiotoxicity [58]. Recently, the Critical Path Institute was incorporated as a "neutral, third party" to serve as a consortium organizer [59] and interface between industry members and the FDA. One of its first efforts was the Predictive Safety Testing Consortium (PSTC) [60,61], with a specific focus on qualification of biomarkers for regulatory use. The PSTC legal agreement addresses issues, such as intellectual property, antitrust concerns, and confidentiality, and thus assures open collaboration in a manner consistent with applicable legal requirements. The PSTC solicited representatives from the FDA and the European Medicines Agency (EMEA) to serve as advisors. As experts in various areas of toxicity, these advisors bring not only their expertise but also the experience of how problems of a given target-organ toxicity are confronted and could be addressed in a regulatory setting. Thus, the development of qualification data is targeted with a keen eye toward what will ultimately support safety decisions in the regulated drug development and regulatory review process.

# DEVELOPMENT OF SERUM CALCIUM AND PHOSPHORUS AS CLINICAL BIOMARKERS FOR DRUG-INDUCED SYSTEMIC MINERALIZATION: CASE STUDY WITH A MEK INHIBITOR

Alan P. Brown, Ph.D., DABT
*Pfizer Global Research and Development, Ann Arbor, Michigan*

## INTRODUCTION

The mitogen-activated protein kinase (MAPK) signal transduction pathways control key cellular processes such as growth, differentiation, and proliferation, and provide a means for transmission of signals from the cell surface to the nucleus. As a part of the RAS–RAF–MEK–MAPK pathway, MEK (MAP kinase kinase) phosphorylates the MAPK proteins ERK1 and ERK2 (extracellular signal-regulated kinases) as a means for intracellular signaling (Sebolt-Leopold, 2000). Although MEK has not been identified as having oncogenic properties, this kinase serves as a focal point in the signal transduction pathway of known oncogenes (e.g., RAS and RAF) (Mansour et al., 1994). MEK exists downstream of various receptor tyrosine kinases (such as the epidermal growth factor receptor) which have been demonstrated to be important in neoplasia (Jost et al., 2001). RAS activation occurs first, followed by recruitment of RAF (A-RAF, B-RAF, or RAF-1) proteins to the cell membrane through binding to RAS, with subsequent activation of RAF. RAF phosphorylates MEK1 and MEK2 on multiple serine residues in the activation

process. MEK1 and MEK2 phosphorylate tyrosine or threonine residues on ERK proteins in the signal transduction process, with phosphorylated ERK activating various transcription factors (Friday and Adjei, 2008). Aberrant activation of this pathway has been observed in a diverse group of solid tumors, along with leukemia, and is believed to play a key role in tumorigenesis (Hoshino et al., 1999; Milella et al., 2001).

Based on a significant amount of preclinical data, development of small-molecule inhibitors of MEK appears to be a rational approach for treatment of various malignancies (Sebolt-Leopold et al., 1999; Dent and Grant, 2001). The first MEK inhibitor to enter clinical trials was CI-1040 (also known as PD0184352), which was intended for oral administration. However, the level of antitumor activity in a multicenter phase II study in patients with various solid tumors was not sufficient to warrant further development of this drug (Rinehart et al., 2004; Wang et al., 2007). CI-1040 exhibited low oral bioavailability and high metabolism, which were primary factors resulting in insufficient plasma drug levels for antitumor activity.

PD0325901 [Figure 1; chemical name of *N*-((*R*)-2,3-dihydroxypropoxy)-3,4-difluoro-2-(2-fluoro-4-iodo-phenylamino)benzamide] is a highly potent and specific non-ATP competitive inhibitor of MEK ($K_i$ of 1 nM against activated MEK1 and MEK2 in vitro), and demonstrated anticancer activity against a broad spectrum of human tumors in murine models (Sebolt-Leopold et al., 2004). Preclinical studies indicate that PD0325901 has the potential to impair growth of human tumors that rely on the MEK/MAPK pathway for growth and survival. PD0325901 inhibits the phosphorylation of MAPK proteins (ERK1 and ERK2) as a biochemical mechanism of action, and assays were developed to evaluate inhibition of protein phosphorylation in normal and neoplastic tissues (Brown et al., 2007). This compound has greatly improved pharmacologic and pharmaceutical properties compared with CI-1040 (i.e.,

**Figure 1** Chemical structure of PD0325901.

greater potency for MEK inhibition, higher bioavailability, and increased metabolic stability) and has significant promise for determining the therapeutic potential for treating cancer with an orally active MEK inhibitor (Rinehart et al., 2004; Sebolt-Leopold et al., 2004). PD0325901 was selected for development as a clinical candidate due to its superior preclinical profile compared to CI-1040 (Wang et al., 2007). Toxicology studies were subsequently initiated to support the conduct of a phase I or II clinical trial in cancer patients with various solid tumors (advanced breast cancer, colon cancer, melanoma, non-small cell lung cancer) utilizing oral administration of the drug.

## TOXICOLOGY STUDIES

The nonclinical safety of PD0325901 was evaluated in Sprague–Dawley rats given single oral or intravenous (IV) doses, in beagle dogs given oral and IV escalating doses, and in cynomolgus monkeys given escalating oral doses to assess acute toxicity and assist in dose selection for subsequent studies. The potential effects of PD0325901 on central nervous system, cardiovascular, and pulmonary function were evaluated in single-dose safety pharmacology studies. Two-week dose-range finder (nonpivotal) oral toxicity studies were conducted in rats, dogs, and monkeys to assist in dose and species selection for the pivotal one-month oral toxicology studies. In addition, an investigative oral toxicity study was conducted in female Balb/c mice. The dog was selected as the nonrodent species for the pivotal toxicology study because of the following data. Metabolites of PD0325901 identified in human liver microsomal incubations were also present following incubation with dog liver microsomes, plasma protein binding of PD0325901 is similar in dogs and humans (>99%), and oral bioavailability in dogs is high (>90%). Finally, injury to the mucosa of the gastrointestinal tract occurred at lower doses and exposures in dogs than in monkeys (based on dose-range-finding studies), indicating the dog as the more sensitive nonrodent species. Pivotal one-month oral toxicity studies, including one-month reversal phases, were conducted in beagle dogs and Sprague–Dawley rats to support submission of an investigational new drug (IND) application to the U.S. Food and Drug Administration. A list of toxicology studies of PD0325901 conducted prior to initiation of human testing is presented in Table 1.

Upon completion of the first two-week dose-range-finding study in rats, a significant and unique toxicity was observed that involved mineralization of vasculature (Figure 2) and various soft tissues (i.e., ectopic or systemic mineralization) as determined by routine light-microscopic evaluation. In a follow-up study in rats, dysregulation of serum calcium and phosphorus homeostasis, and systemic mineralization occurred in a time- and dose-dependent manner. This toxicity was not observed in dogs or monkeys, despite systemic exposures to PD0325901 more than 10-fold higher than those associated with mineralization in rats and pharmacologic inhibition of

phosphorylated MAPK in canine or monkey tissue (demonstrating biochemical activity of PD0325901 at the target protein, i.e., MEK). Various investigative studies were conducted to examine the time course and potential mechanism of systemic mineralization in rats and to identify biomarkers that could be used to monitor for this effect in clinical trials. Next we describe the key studies conducted to investigate this toxicity, the results obtained, and how the nonclinical data were utilized to evaluate the safety risk of the compound, select a safe starting dose for a phase I trial, and provide measures to ensure patient safety during clinical evaluation of PD0325901 in cancer patients.

**Figure 2** Mineralization of the aorta in a male rat administered PD0325901 at 3 mg/kg in a dose-range-finding study. Arrows indicate mineral in the aorta wall. Hematoxylin and eosin–stained tissue section. (*See insert for color reproduction of the figure.*)

At the beginning of the toxicology program for PD0325901, a two-week oral-dose-range-finding study was conducted in male and female rats in which daily doses of 3, 10, and 30 mg/kg (18, 60, and 180 mg/m$^2$, respectively) were administered. Mortality occurred in males at ≥3 mg/kg and females at ≥10 mg/kg, with toxicity occurring to a greater extent in males at all dose levels. Increased serum levels of phosphorus (13 to 69%), and decreased serum total protein (12 to 33%) and albumin (28 to 58%) were seen at all doses. Light-microscopic evaluation of formalin-fixed and hematoxylin- and eosin-stained tissues was performed. Mineralization occurred in the aorta (Figure 2) and coronary, renal, mesenteric, gastric, and pulmonary vasculature of males at ≥3 mg/kg and in females at ≥10 mg/kg. Parenchymal mineralization with associated degeneration occurred in the gastric mucosa and muscularis, intestines (muscularis, mucosa, submucosa), lung, liver, renal cortical tubules, and/or myocardium at the same doses. Use of the Von Kossa histology stain indicated the presence of calcium in the mineralized lesions. Vascular/parenchymal mineralization and degeneration were generally dose related in incidence and severity. PD0325901 produced increased thickness (hypertrophy) of the femoral growth plate (physis) in both sexes at all doses, and degeneration and necrosis of the femoral metaphysis in males at ≥3 mg/kg and females at 30 mg/kg. In addition, skin ulceration, hepatocellular necrosis, decreased crypt goblet cells, reduced hematopoetic elements, and ulcers of cecum and duodenum were observed. Systemic mineralization of the vasculature and soft tissues was

the most toxicologically significant finding of this study. At this time, it was not known whether the hyperphosphatemia was due to decreased renal clearance (York and Evans, 1996) and/or related to the mineralization. However, hyperphosphatemia and elevated serum calcium–phosphorus (Ca × P) product can result in vascular and/or soft tissue mineralization (Spaulding and Walser, 1970; Block, 2000; Giachelli et al., 2001). In addition, morphologic findings similar to those seen in this study are observed in various animal species (e.g., dogs, horses, pigs, rats) with vitamin D toxicosis and altered calcium homeostasis (Grant et al., 1963; Spangler et al., 1979; Harrington and Page, 1983; Long, 1984). Tissue mineralization is observed in the aorta, various arteries, myocardium, gastric mucosa, and renal tubules, along with other soft tissues in these animals.

An exploratory two-week oral toxicity study was next conducted in male and female rats to further investigate the toxicities observed in the initial two-week dose-range finder. The objectives of this study were to identify a minimal or no-adverse-effect level and to provide toxicity, toxicokinetic, and pharmacodynamic data to aid in dose selection for future studies. In addition, an attempt was made to assess whether alterations in phosphorus and calcium homeostasis occur and whether changes can be monitored as potential biomarkers of toxicity. Doses tested in this study were 0.3, 1, or 3 mg/kg (1.8, 6, or 18 mg/m$^2$, respectively) and animals were dosed for up to 14 days. Cohorts of animals (5/sex/group) were necropsied on days 4 and 15, and hematology, serum biochemistry, plasma intact parathyroid hormone (PTH), and urinary parameters were evaluated. Urinalysis included measurement of calcium, phosphorus, and creatinine levels. Select tissues were examined microscopically, and samples of liver and lung were evaluated for total and phosphorylated MAPK (pMAPK) levels by Western blot analysis to evaluate for pharmacologic activity of PD0325901 (method described in Brown et al., 2007). Satellite animals were included for plasma drug-level analyses on day 8. In this study, systemic mineralization occurred at ≥0.3 mg/kg in a dose-dependent fashion, was first observed on day 4, and was more severe in males. By day 15, mineralization was generally more pronounced and widespread. Skeletal changes included hypertrophy of the physeal zone in males at ≥1 mg/kg and at 3 mg/kg in females, and necrosis of bony trabeculae and marrow elements with fibroplasia, fibro-osseous proliferation, and/or localized hypocellularity at ≥1 mg/kg in males and 3 mg/kg in females. The minimal plasma PD0325901 AUC(0–24) values associated with toxicity were 121 to 399 ng · h/mL, which were well below exposure levels associated with antitumor efficacy in murine models (AUC of 1180 to 1880 ng · h/mL). Pharmacologic inhibition of tissue pMAPK occurred at ≥1 mg/kg and was not observed in the absence of toxicity. The gastric fundic mucosa appeared to be the most sensitive tissue for evaluating systemic mineralization, which probably resulted from alterations in serum calcium and phosphorus homeostasis. This was based on the following observations. On day 4, serum phosphorus levels were increased 12

**TABLE 2 Mean Clinical Chemistry Changes in Male Rats Administered PD0325901 for Up to 2 Weeks**

to 26%, and albumin was decreased 17 to 26% at ≥1 mg/kg (Table 2, male data only). In addition, PTH levels were decreased in a dose-dependent fashion (60 to 77%) at ≥1 mg/kg. On day 15, phosphorus levels were increased 21% in males at 3 mg/kg, and albumin was decreased 8 to 32% at ≥0.3 mg/kg. PTH levels were decreased 77 to 89% at 3 mg/kg. Changes in urinary excretion of calcium and phosphorus were observed in both sexes at ≥1 mg/kg and included increased excretion of phosphorus on day 15. Although increases in excretion of calcium were observed on day 4 in females, males exhibited decreases in urinary calcium. In this study, PD0325901 administration resulted in significantly decreased levels of serum albumin without changes in serum (total) calcium levels (Payne et al., 1979; Meuten et al., 1982; Rosol and Capen, 1997). This indicates that free, non-protein-bound calcium levels were increased. Hyperphosphatemia and hypercalcemia result in an increased Ca × P product, which is associated with induction of vascular mineralization (Block, 2000; Giachelli et al., 2001). The changes observed in urinary excretion of calcium and phosphorus probably reflected the alterations in serum levels.

After completion of the two studies in rats described above it was concluded that PD0325901 produces significant multiorgan toxicities in rats with no margin between plasma drug levels associated with antitumor efficacy, pharmacologic inhibition of pMAPK (as an index of MEK inhibition), and toxicity in rats. Systemic mineralization was considered the preclinical toxicity of greatest concern, due to the severity of the changes observed and expectation of irreversibility, and the data suggested that it was related to a dysregulation in serum phosphorus and calcium homeostasis. Furthermore, skeletal lesions were seen in the rat studies that were similar to those reported with vitamin D toxicity and may be related to the calcium–phosphorus dysregulation. In concurrent toxicology studies in dogs and monkeys, neither systemic

mineralization nor skeletal changes were observed, despite higher plasma drug exposures, lethal doses, or pharmacologic inhibition of MEK. Therefore, the following questions were posed regarding PD0325901-induced systemic mineralization: (1) What is a potential mechanism? (2) Is this toxicity relevant to humans or rat-specific? and (3) Can this toxicity be monitored clinically?

The ability of an anticancer agent that modulates various signal transduction pathways to produce dysregulation in serum calcium homeostasis is not unprecedented. 8-Chloro-cAMP is an experimental compound that has been shown to modulate various protein kinase signal transduction pathways involved in neoplasia. In preclinical models, this compound produced growth inhibition and increased differentiation in cancer cells (Ally et al., 1989). In a clinical trial, 8-chloro-cAMP was administered to patients with advanced cancer via intravenous infusion and resulted in dose-limiting toxicity of reversible hypercalcemia, as serum calcium was increased by up to approximately 40% (Saunders et al., 1997). This drug produced a parathyroid hormone-like effect in these patients, resulting in increased synthesis of 1,25-dihydroxyvitamin D (up to 14 times baseline value) as a mechanism for the hypercalcemia. Intravenous administration of 8-chloro-cAMP to beagle dogs also resulted in hypercalcemia (serum calcium increased 37 to 46%), indicating similar actions across species (Brown et al., 2000). Experience with this compound was important with respect to designing investigative studies with PD0325901 in which the hormonal control of serum calcium and phosphorus were evaluated.

An investigative study was designed in rats to examine the time course for tissue mineralization in target organs and to determine whether clinical pathology changes occur prior to, or concurrent with, lesion development (Brown et al., 2005a). These clinical pathology parameters may therefore serve as biomarkers for systemic mineralization. Male rats (15/group) were used due to their increased sensitivity for this toxicity compared with females. Oral doses tested were 1, 3, or 10 mg/kg (6, 18, or 60 mg/m$^2$, respectively). Five animals per group were necropsied on days 2, 3, or 4 following 1, 2, or 3 days of treatment, respectively. Clinical laboratory tests were conducted at necropsy that included serum osteocalcin, urinalysis, and plasma intact PTH, calcitonin, and 1,25-dihydroxyvitamin D. Lung samples were evaluated for inhibition of pMAPK, and microscopic evaluations of the aorta, distal femur with proximal tibia, heart, and stomach were conducted for all animals.

Administration of PD0325901 resulted in inhibition of pMAPK in lung at all doses, demonstrating pharmacologic activity of the drug. On day 2, mineralization of gastric fundic mucosa and multifocal areas of necrosis of the ossifying zone of the physis were present only at 10 mg/kg. Necrosis of the metaphysis was present at ≥3 mg/kg. Serum phosphorus levels increased 33 to 43% and 1,25-dihydroxyvitamin D increased two- to sevenfold at all doses (Table 3). Osteocalcin increased 14 to 18%, and serum albumin decreased 8 to 14% at ≥3 mg/kg (Table 4). Osteocalcin is a major noncollagenous protein of bone matrix and synthesized by osteoblasts (Fu and Muller, 1999). Changes in serum osteocalcin can reflect alterations in bone turnover (resorption/

formation). Serum osteocalcin appears to reflect the excess of synthesized protein not incorporated into bone matrix, or released protein during bone resorption (Ferreira and Drueke, 2000). The increases in osteocalcin seen in this study may have been reflective of bone necrosis.

On day 3, mineralization of gastric fundic mucosa, gastric and cardiac arteries, aorta, and heart were present in all rats at 10 mg/kg. Myocardial necrosis was also seen at 10 mg/kg. Mineralization of gastric fundic mucosa was present in all rats at 3 mg/kg, and focal, minimal myocyte necrosis was present in one rat at 3 mg/kg. Thickening of the physeal zone of hypertrophying cartilage, and necrosis within the physeal zone of ossification and in the metaphyseal region in femur and tibia were seen in all animals at 10 mg/kg. Necrosis within the metaphyseal region was also present at 3 mg/kg. Serum phosphorus increased 13 to 66% at all doses and 1,25-dihydroxyvitamin D increased two- to fourfold at ≥3 mg/kg. Osteocalcin increased 12 to 28% at ≥3 mg/kg and serum albumin was decreased (7 to 19%) at all doses. Urine calcium increased

fivefold at 10 mg/kg, resulting in a fivefold increase in urine calcium/creatinine ratio. This increase may have represented an attempt to achieve mineral homeostasis in response to the hypercalcemia. In addition, hypercalciuria can occur with vitamin D intoxication (Knutson et al., 1997).

On day 4, mineralization of gastric fundic mucosa, gastric muscularis, gastric and cardiac arteries, aorta, and heart were present in the majority of animals at ≥3 mg/kg. Myocardial necrosis with accompanying neutrophilic inflammation was also seen in all rats at 10 mg/kg and in one animal at 3 mg/kg. Mineralization of gastric fundic mucosa was present at 1 mg/kg. Thickening of the physeal zone of hypertrophying cartilage, and necrosis within the physeal zone of ossification and/or in the metaphyseal region in femur and tibia, were present at ≥3 mg/kg. At 1 mg/kg, thickening of the physeal zone of hypertrophying cartilage and metaphyseal necrosis were observed. Serum phosphorus increased 16 to 91% at all doses and 1,25-dihydroxyvitamin D increased two- to fivefold at ≥3 mg/kg. Osteocalcin increased 14 to 24% at ≥3 mg/kg, and serum albumin decreased 19 to 32% at all doses. At 10 mg/kg, serum calcium was decreased 31% (possibly resulting from the hypercalciuria on day 3) and calcitonin was decreased by 71%. Calcitonin is secreted by the thyroid gland and acts to lower serum calcium levels by inhibiting bone resorption (Rosol and Capen, 1997). The decrease in calcitonin may have resulted from feedback inhibition due to low serum calcium levels at 10 mg/kg on day 4. Urine creatinine, calcium, and phosphorus were increased at 10 mg/kg. This resulted in decreases of 41% and 21% in the calcium/creatinine and phosphorus/creatinine ratios, respectively.

This four-day investigative study in rats resulted in several very important conclusions which were critical for supporting continued development of PD0325901. In the study, PD0325901 at ≥1 mg/kg resulted in systemic mineralization and skeletal changes in a dose- and time-dependent fashion. These changes were seen after a single dose at 10 mg/kg and after 3 doses at 1 mg/kg. Elevations in serum phosphorus and plasma 1,25-dihydroxyvitamin D occurred prior to tissue mineralization. Although serum albumin was decreased throughout the study, calcium remained unchanged, consistent with an increase in non-protein-bound calcium. This study set the stage for the proposal of using serum phosphorus and calcium measurements as clinical laboratory tests or biomarkers for PD0325901-induced systemic mineralization. Whereas measurement of plasma 1,25-dihydroxyvitamin D is technically complex and costly, evaluation of serum calcium and phosphorus is rapid and performed routinely in the clinical laboratory with historical reference ranges readily available. Although the data obtained with urinalysis were consistent with dysregulation of calcium and phosphorus homeostasis, concerns existed as to whether specific and reproducible urinalysis parameters could be developed for monitoring the safety of PD0325901. Based on the data obtained thus far, hyperphosphatemia appeared to be the primary factor for eliciting tissue mineralization, and serum phosphorus was proposed as the key analyte for monitoring.

An investigative study was conducted in male rats to assess the reversibility of serum chemistry changes following a single oral dose of PD0325901 (Brown et al., 2005a). The hypothesis was that serum phosphorus levels would return to control levels in the absence of drug administration. Male rats (10/group) received single oral doses at 1, 3, or 10 mg/kg, with controls receiving vehicle alone. Blood was collected on days 2, 3, 5, and 8 for serum chemistry analysis. Hyperphosphatemia (serum phosphorus increased up to 58%) and minimal increases in calcium occurred at all doses on days 2 and 3. Albumin was decreased at 10 mg/kg. These changes were completely reversible within a week. This study demonstrated that increases in serum phosphorus and calcium induced by PD0325901 are reversible following cessation of dosing. Although a single dose of 10 mg/kg produces systemic mineralization in rats, withdrawal of dosing results in normalization of serum calcium and phosphorus levels, indicating that the homeostatic mechanisms controlling these electrolytes remain intact. The results of this study were not unexpected. Oral administration to dogs of the vitamin D analogs dihydrotachysterol and Hytakerol (dihydroxyvitamin $D_2$-II) results in hypercalcemia that is reversible following termination of dosing (Chen et al., 1962). Reversal of hypercalcemia and hypercalciuria has been demonstrated in humans following cessation of dosing of various forms of vitamin D (calciferol, dihydrotachysterol, 1-α-hydroxycholecalciferol, or 1-α,25-dihydroxycholecalciferol) (Kanis and Russell, 1977).

Another investigative study was conducted in male rats to determine whether pamidronate (a bisphosphonate) or Renagel (sevelamer HCl; a phosphorus binder) would inhibit tissue mineralization induced by PD0325901 by inhibiting hyperphosphatemia. Bisphosphonates inhibit bone resorption and in so doing modulate serum calcium and phosphorus levels. Renagel is a nonabsorbable resin that contains polymers of allylamine hydrochloride, which forms ionic and hydrogen bonds with phosphate in the gut. Rats received daily oral doses of PD0325901 at 3 mg/kg for 14 days with or without co-treatment with pamidronate or Renagel. Pamidronate was given twice intravenously at 1.5 mg/kg one day prior to PD0325901 dosing and on day 6. Renagel was given daily as 5% of the diet beginning one day prior to PD0325901 dosing. Treatment groups consisted of oral vehicle alone, PD0325901 alone, pamidronate alone, Renagel alone, PD0325901 + pamidronate, and PD0325901 + Renagel. PD0325901 plasma AUC(0–24) values were 11.6, 9.17, and 4.34 μg·h/mL in the PD0325901 alone, PD0325901 + pamidronate, and PD0325901 + Renagel groups, respectively. Administration of PD0325901 alone resulted in hyperphosphatemia on days 3 and 15, which was inhibited by co-treatment with pamidronate or Renagel on day 3 only. PD0325901 alone resulted in systemic mineralization and skeletal changes consistent with changes seen in previous rat studies. Coadministration with either pamidronate or Renagel protected against systemic mineralization on day 3 only. Bone lesions were decreased with the co-treatments. Inhibition of toxicity with Renagel may have been due in part to decreased systemic drug exposure. However, the inhibition of toxic-

ity with pamidronate supports the role of a calcium–phosphorus dysregulation in PD0325901-induced systemic mineralization, because the inhibition of systemic mineralization observed on day 3 coincided with attenuation in the rise in serum phosphorus in these animals.

A two-week oral dose range-finding study was conducted in dogs in which doses tested were 0.2, 0.5, and 1.5 mg/kg (4, 10, and 30 mg/m$^2$, respectively). Also, a two-week oral-dose-range-finding study was conducted in cynomolgus monkeys at doses of 0.5, 3, and 10 mg/kg (6, 36, and 120 mg/m$^2$, respectively). In addition to standard toxicology and toxicokinetic endpoints, determination of inhibition of tissue and peripheral blood mononuclear cell pMAPK was performed to assess pharmacologic activity of PD0325901 in both studies. PTH and 1,25-dihydroxyvitamin D were evaluated in the monkey study. In both studies, mortality occurred at ≥0.5 mg/kg (dogs) and at 10 mg/kg (monkeys) due to injury to the gastrointestinal tract mucosa, inhibition of pMAPK occurred at all doses, and systemic mineralization was not observed in either study. Increases in serum phosphorus were seen in moribund animals and/or associated with renal hypoperfusion (resulting from emesis, diarrhea, and dehydration). These elevations in phosphorus were considered secondary to renal effects and were not associated with changes in serum calcium. Toxicologically significant increases in serum phosphorus or calcium were not evident at nonlethal doses in dogs or monkeys. In the two-week monkey study, a dose-related increase in 1,25-dihydroxyvitamin D was observed on day 2 only (after a single dose) at ≥3 mg/kg. This increase did not occur on days 7 or 15, and was not associated with changes in serum phosphorus or calcium, nor systemic mineralization. Therefore, there did not appear to be toxicologic significance to the day 2 increase in 1,25-dihydroxyvitamin D in monkeys.

## DISCUSSION

Mineralization of vasculature and various soft tissues (systemic mineralization) was observed in toxicology studies in rats in a time- and dose-dependent manner. This change was consistent with the presence of calcium–phosphorus deposition within the vascular wall and parenchyma of tissues such as the stomach, kidney, aorta, and heart. The stomach appeared to be the most sensitive tissue, since mineralization of gastric fundic mucosa occurred prior to the onset of mineralization in other tissues. Male rats were consistently more sensitive to this toxicity than were female rats. In the pivotal one-month toxicity study in rats, the no-effect level for systemic mineralization was 0.1 mg/kg (0.6 mg/m$^2$) in males and 0.3 mg/kg (1.8 mg/m$^2$) in females, which were associated with PD0325901 steady-state plasma AUC(0–24) values of 231 and 805 ng·h/mL, respectively. Systemic mineralization was not observed in dogs or monkeys, despite pharmacologic inhibition of tissue pMAPK levels (>70%), administration of lethal doses, and exposures greater than 10-fold of those that induced mineralization in rats (10,600 ng·h/mL in dogs and

up to 15,000 ng · h/mL in monkeys). Systemic mineralization was not observed in mice despite administration of PD0325901 at doses up to 50 mg/kg (150 mg/m$^2$).

Systemic mineralization observed in rats following administration of PD0325901 is consistent with vitamin D toxicity due to dysregulation in serum calcium and phosphorus homeostasis (Grant et al., 1963; Rosenblum et al., 1977; Kamio et al., 1979; Mortensen et al., 1996; and Morrow, 2001). A proposed hypothesis for the mechanism of this toxicity is depicted in Figure 3. Elevated serum phosphorus levels (hyperphosphatemia) and decreased serum albumin were observed consistently in rats administered PD0325901. Although serum albumin levels are decreased in rats treated with PD0325901, calcium values typically remain unchanged or slightly elevated in these animals, indicating that free, non-protein-bound calcium is increased (Rosol and Capen, 1997; Payne et al., 1979; Meuten et al., 1982). Decreased parathyroid hormone levels (PTH) were observed in the rat studies. PTH plays a central role in the hormonal control of serum calcium and phosphorus. PTH is produced by the parathyroid gland and induces conversion of 25-hydroxyvitamin D (which is produced in the liver) to 1,25-dihydroxyvitamin D (calcitriol) in the kidney. 1,25-Dihydroxyvitamin D elicits increased absorption of calcium from the gastrointestinal tract. In addition, PTH mobilizes calcium and phosphorus from bone by increasing bone resorption, increases renal absorption of calcium, and increases renal excretion of phosphorus (in order to regulate

**Figure 3** Hypothesis for the mechanism for systemic mineralization in the rat following PD0325901 administration.

serum phosphorus levels). Elevations in serum calcium typically elicit decreased PTH levels as a result of the normal control (negative feedback loop) of this endocrine system (Rosol and Capen, 1997). The decreases in PTH observed in the rats were believed to be due to the elevations in serum calcium (hypercalcemia). Hyperphosphatemia in the presence of normo- or hypercalcemia can result in an increased Ca × P product, which is associated with systemic mineralization (Block, 2000). Hyperphosphatemia was also observed in rats administered PD176067, which is a reversible and selective inhibitor of fibroblast growth factor receptor tyrosine kinase. In these animals, vascular and soft tissue mineralization also occurs (aorta and other arteries, gastric fundic mucosa, myocardium, renal tubules), probably due to increased Ca × P product (Brown et al., 2005b).

Administration of PD0325901 to rats resulted in significantly increased levels of plasma 1,25-dihydroxyvitamin D. The mechanism for this action is not known but is not believed to be due to a metabolite of PD0325901. This is the most potent form of vitamin D and the primary metabolite responsible for regulating serum calcium and phosphorus. Vitamin D is converted to 25-hydroxyvitamin D in the liver and then 1-hydroxylated to 1,25-dihydroxyvitamin D in renal tubules. 1,25-Dihydroxyvitamin D acts by increasing absorption of calcium and phosphorus from the gastrointestinal tract, and can increase calcium and phosphorus reabsorption by renal tubules. Hyperphosphatemia and increased plasma 1,25-dihydroxyvitamin D levels in rats occurred 1 to 2 days prior to the detection of tissue mineralization at doses ≤3 mg/kg (18 mg/m$^2$).

Administration of PD0325901 to rats resulted in bone lesions that included necrosis of the metaphysis and the ossifying zone of the physis, and thickening of the zone of hypertrophying cartilage of the physis. The expansion of chondrocytes in the physis may be a response to the metaphyseal necrosis and loss of osteoprogenitor cells. These changes are characterized by localized injury to bone that appear to be due to local ischemia and/or necrosis. Skeletal vascular changes may be present in these animals, resulting in disruption of endochondral ossification. Skeletal lesions, including bone necrosis, can result from vitamin D intoxication (Haschek et al., 1978). The skeletal lesions observed in rats administered PD0325901 are similar to those reported with vitamin D toxicity, which provides additional evidence that toxicity occurred via induction of 1,25-dihydroxyvitamin D. Bone lesions similar to those observed in rats were not seen in dogs, monkeys, or mice administered PD0325901.

In summary, PD0325901-induced systemic mineralization in the rat results from a dysregulation in serum phosphorus and calcium homeostasis. This dysregulation appears to result from toxicologically significant elevations in plasma 1,25-dihydroxyvitamin D levels following drug administration. Based on the toxicology data, rats are uniquely sensitive to this toxicity. A summary of the primary target organ toxicities observed in the preclinical studies is presented in Table 5. Toxicity to the skin (epidermal lesions) and gastrointes-

tinal tract (primarily ulcers/erosions in the mucosa) were observed across species and may have resulted from inhibition of MEK-related signal transduction pathways in these tissues (Brown et al., 2006). Gastrointestinal tract toxicity is dose-limiting in dogs and monkeys and was anticipated to be the dose-limiting toxicity of PD0325901 in the clinic. Therefore, gastrointestinal tract toxicity may preclude the development of other potential adverse events in humans, including potential dysregulation in serum phosphorus or calcium. It is not known whether systemic mineralization is relevant to humans. However, if PD0325901 does induce a dysregulation in serum calcium–phosphorus metabolism in humans, monitoring serum levels would provide an early indication of effects and guide modifications to dosing regimens.

To ensure patient safety in the phase I clinical trial with PD0325901, procedures were incorporated into the trial design to monitor for potential dysregulation in serum calcium–phosphorus homeostasis. Measurements of serum calcium, phosphorus, creatinine, albumin, and blood urea nitrogen were performed frequently during the initial treatment cycle (21 days of dosing in a 28-day cycle), with periodic measurement in subsequent cycles, and the serum Ca × P product was calculated. The serum Ca × P product has been determined to be a clinically useful value as a means for evaluating risk for tissue and/or vascular mineralization with the recommendation that the value not exceed 70 based on clinical use of vitamin D analogs such as Rocaltrol and Hectorol (Roche Laboratories, 1998; Bone Care International, Inc., 1999; Block, 2000). Serum calcium and phosphorus are readily measured in a clinical setting with well-established reference ranges available. The trial included a protocol-specific dose-limiting toxicity for a Ca × P product > 70, which required a confirmatory measurement and dose interruption for that patient. In addition, serum vitamin D, PTH, alkaline phosphatase (total and bone), osteocalcin, and urinary C- and N-terminal peptide of collagen 1 (markers of bone resorption) were included for periodic measurement. Criteria considered for exclusion of candidate patients from the clinical trial included a history of

malignancy-associated hypercalcemia, extensive bone metastasis, parathyroid disorder, hyperphosphatemia and renal insufficiency, serum calcium or phosphorus levels >1× the upper limit of normal, and/or concomitant use of calcium supplements and vitamin D in amounts exceeding normal daily allowances.

## CALCULATION OF CLINICAL STARTING DOSE

The currently accepted algorithm for calculating a starting dose in clinical trials with oncology drugs is to use one-tenth of the dose that causes severe toxicity (or death) in 10% of the rodents ($STD_{10}$) on a mg/m$^2$ basis, provided that this starting dose (i.e., 1/10 the $STD_{10}$) does not cause serious, irreversible toxicity in a nonrodent species (in this case, the dog) (DeGeorge et al., 1998). If irreversible toxicities are induced at the proposed starting dose in nonrodents or if the nonrodent (i.e., the dog) is known to be the more appropriate animal model, the starting dose would generally be one-sixth of the highest dose tested in the nonrodent (the dog) that does not cause severe, irreversible toxicity.

Calculation of the initial phase I starting dose of PD0325901 was based on the pivotal one-month toxicology studies in rats and dogs. Doses tested in the one-month rat study were 0.1, 0.3, and 1 mg/kg (0.6, 1.8, and 6 mg/m$^2$, respectively), and doses in the one-month dog study were 0.05, 0.1, and 0.3 mg/kg (1, 2, and 6 mg/m$^2$, respectively). Both studies included animals assigned to a one-month reversal phase, in the absence of dosing, to assess reversibility of any observed toxicities. In addition to standard toxicology and toxicokinetic parameters, these studies included frequent evaluation of serum chemistries, and measurement of vitamin D, osteocalcin, PTH, and inhibition of tissue pMAPK levels.

In the one-month rat study, no drug-related deaths occurred and systemic mineralization occurred in multiple tissues in both sexes at 1 mg/kg. Hypocellularity of the metaphyseal region of distal femur and/or proximal tibia occurred in males at 1 mg/kg. Toxicologic findings at lower doses included skin sores (at ≥0.1 mg/kg) and mineralization of gastric mucosa in one male at 0.3 mg/kg. The findings at ≤0.3 mg/kg were not considered to represent serious toxicity. In previous two-week dose-range-finding studies in rats, death occurred at 3 mg/kg (18 mg/m$^2$), indicating this to be the minimal lethal dose in rats. Based on these results, the $STD_{10}$ in rats was determined to be 1 mg/kg (6 mg/m$^2$)

In the one-month dog study, doses up to 0.3 mg/kg (6 mg/m$^2$) were well tolerated with minimal clinical toxicity. Primary drug-related toxicity was limited to skin sores in two animals at 0.3 mg/kg. One-tenth the $STD_{10}$ in rats is 0.6 mg/m$^2$, which is well below a minimally toxic dose (6 mg/m$^2$) in dogs. These data indicate an acceptable phase I starting dose to be 0.6 mg/m$^2$, which is equivalent to 1 mg in a 60-kg person. The relationships between the primary toxicities in rats and dogs with dose and exposure are presented in Figure 4.

**Figure 4** Relationships between dose and exposure with the primary toxicities of PD0325901 in rats and dogs. Exposure is expressed as PD0325901 plasma AUC(0–24) in ng · hr/mL and dose in mg/m$^2$. Results from nonpivotal (dose-range-finding) studies and the pivotal one-month toxicity studies are presented.

In the phase I trial of PD0325901 in cancer patients (melanoma, breast, colon, and non-small cell lung cancer), oral doses were escalated from 1 to 30 mg twice daily (BID). Each treatment cycle consisted of 28 days, and three schedules of administration were evaluated: (1) 3 weeks of dosing with one week off, (2) dosing every day, and (3) 5 days of dosing with 2 days off per week (LoRusso et al., 2005; Menon et al., 2005; Tan et al., 2007; LoRusso et al., 2007). Doses ≥2 mg BID suppressed tumor pMAPK (indicating biochemical activity of the drug) and acneiform rash was dose limiting in one patient at 30 mg BID. There were no notable effects on serum Ca × P product and the most common toxicities included rash, fatigue, diarrhea, nausea, visual disturbances and vomiting. Acute neurotoxicity was frequent in patients receiving ≥15 mg BID (all schedules) and several patients developed optic nerve ischemia, optic neuropathy, or retinal vein occlusion (LoRusso et al., 2007). In the phase I trial, there were three partial responses (melanoma) and stable disease in 24 patients (primarily melanoma) (LoRusso et al., 2007). In a pilot phase II study of PD0325901 in heavily pretreated patients with non-

small cell lung cancer, 15 mg BID was given on various schedules over a 28-day cycle (Haura et al., 2007). The main toxicities were reversible visual disturbances, diarrhea, rash, and fatigue. The mean trough concentration of PD0325901 at 15 mg BID was 108 ng/mL (at steady state) and there were no objective responses (Haura et al., 2007).

## CONCLUSIONS

Tissue mineralization produced in rats administered the MEK inhibitor PD0325901 provides a case study of how a unique and serious toxicity observed in preclinical safety testing was effectively managed to allow progression of an experimental drug into human clinical trials. A number of key factors were critical for allowing continued development of this compound to occur, rather than early termination. PD0325901 represented a novel and targeted therapeutic agent for the treatment of various solid tumors, thereby allowing a high risk–benefit ratio to exist due to the significant unmet medical need posed by cancer. Phase I oncology trials typically occur in cancer patients with limited treatment options. Therefore, the barriers to entry for novel anticancer agents in the clinic are generally lower than for phase I trials involving healthy volunteers and therapies for non-life-threatening indications.

Early in the toxicology program with PD0325901, lesions observed in rats were similar to those seen with vitamin D toxicity, and serum chemistry data indicated changes in phosphorus and calcium. This information provided the basis for the hypotheses to be proposed regarding the mechanism for vascular and soft tissue mineralization. Because mineralization occurred in rats administered PD0325901 rather than only in dogs or monkeys, an animal model suitable for multiple investigative studies was readily available. Despite the apparent species specificity for this toxicity, it was not appropriate to discount the risks toward humans because of a "rat-specific" finding. Rather, it was important to generate experimental data that characterized the toxicity and provided a plausible mechanism as a basis for risk management. Studies conducted with PD0325901 examined the dose–response and exposure–response relationships for toxicity and pharmacologic inhibition of MEK, the time course for lesion development, whether the changes observed were reversible or not, and whether associations could be made between clinical laboratory changes and anatomic lesions. We were able to identify biomarkers for tissue mineralization that were specifically related to the mechanism, were readily available in the clinical setting, noninvasive, and had acceptable assay variability. It is important that biomarkers proposed for monitoring for drug toxicity be scientifically robust and obtainable, and meet expectations of regulatory agencies. Finally, the data generated during the preclinical safety evaluation of PD0325901 were used to design the phase I–II clinical trial to ensure patient safety. This included selection of a safe starting dose for phase I,

criteria for excluding patients from the trial, and clinical laboratory tests to be included as biomarkers for calcium–phosphorus dysregulation and tissue mineralization. In conclusion, robust data analyses, scientific hypothesis testing, and the ability to conduct investigative work were key factors in developing a biomarker for a serious preclinical toxicity, thereby allowing clinical investigation of a novel drug to occur.

# BIOMARKERS FOR THE IMMUNOGENICITY OF THERAPEUTIC PROTEINS AND ITS CLINICAL CONSEQUENCES

Claire Cornips, B.Sc., and Huub Schellekens, M.D.
*Utrecht University, Utrecht, The Netherlands*

## INTRODUCTION

Therapeutic proteins such as growth factors, hormones, monoclonal antibodies (mAbs), and others have increased in use dramatically over the past two decades, although their first use dates back more than a century, when animal antisera were introduced for the treatment and prevention of infections. Therapeutic proteins have always been associated with immunogenicity, although the incidence differs widely [1]. Granulocyte colony-stimulating factor (G-CSF) is the only protein in clinical use that has not been reported to induce antibodies. The first proteins used in medicine around 1900 were of animal origin. As foreign proteins they induced high levels of antibodies in the majority of patients after a single or a few injections. The type of immunological response induced was identical to that seen with vaccines.

Most of the therapeutic proteins introduced in recent decades are homologs of human proteins. However, in contrast to expectations, these proteins also appear to induce antibodies, and in some cases, in the majority of patients. Given that these antibodies are directed against auto-antigens, the immunological reaction involves breaking B-cell tolerance.

## MECHANISMS OF ANTIBODY INDUCTION

There are two main mechanisms by which antibodies are induced by therapeutic proteins (Table 1). If the proteins are of completely of foreign origin, such as asparginase or streptokinase, and the first generation mAbs derived from murine cells or partly foreign such as chimeric or humanized mAbs, the antibody response is comparable to a vaccination reaction. Often a single injection is sufficient to induce high levels of neutralizing antibodies, which may persist for a considerable length of time.

The other mechanism is based on breaking B-cell tolerance, which normally exists, to self-antigens, such as human immunoglobulins or products such as epoetins and the interferons. For breaking B-cell tolerance, prolonged exposure to proteins is necessary. In general, it takes months before patients produce antibodies, which are mainly binding and disappear when treatment is stopped.

To induce a classical immune reaction a degree of nonself is necessary. The trigger for this type of immunogenicity is the divergence from the comparable human proteins. The triggers for breaking tolerance are quite different. The production of these auto-antibodies may occur when the self-antigens are exposed to the immune system in combination with a T-cell stimulus or danger signal such as bacterial endotoxins, microbial DNA rich in GC motifs or denatured proteins. This mechanism explains the immunogenicity of biopharmaceuticals containing impurities. When tolerance is broken with this type of mechanism, the response is often weak with low levels of antibodies with low affinity.

To induce high levels of IgG, the self-antigens should be presented to the immune system in a regular array form with a spacing of 50 to 100 Å, a supramolecular structure resembling a viral capsid [2]. Apparently the immune system has been selected to reach vigorously to these types of structures which

**TABLE 1 Main Markers of Immunogenicity of Therapeutic Proteins**

| | Product | Preclinical | Treatment | Patients |
|---|---|---|---|---|
| (Partly) foreign proteins inducing a classical immune response | Level of nonself<br>Presence of T-cell epitopes<br>Biological activity of the product | — | — | Lack of immune tolerance<br>Concomitant therapy |
| Self-protein breaking tolerance | Presence of aggregates<br>Biological activity of the product | Induction of an immune response in immune-tolerant mice | Chronic treatment | Nonimmune compromised<br>Concomitant therapy |

normally are found only in viruses and other microbial agents. The most important factor in the immunogenicity of therapeutic proteins which are human homologs has been the presence of aggregates [3]. Aggregates may be presenting the self-antigens in a repeating form which is such a potent inducer of auto-antibodies.

## FACTORS INFLUENCING IMMUNOGENICITY

So the primary factors inducing an antibody response are aggregates in the case of human proteins and the degree of nonself in (partly) nonhuman proteins. There are also cases in which the immune response cannot be explained. There are, however, a number of other factors that may influence the level of the immune response [4]:

- Product characteristics
  1. Biological function
  2. Impurities and contaminants
  3. Product modification
- Treatment characteristics
  1. Length of treatment
  2. Route of administration
  3. Dosage
  4. Concomitant therapy
- Patient characteristics
  1. Genetic background
  2. Type of disease
  3. Age
  4. Gender
- Unknown factors

### Product Characteristics

The biological activities of the product are influencing the immune response. An immune stimulating therapeutic protein is more likely to induce antibodies than an immune suppressive protein. Monoclonal antibodies targeted to cell-bound epitopes are more likely to induce an immune response than monoclonal antibodies with a target in solution. Also, the Fc-bound activities of monoclonal antibodies have an influence.

Impurities may influence immunogenicity. The immunogenicity of products as human growth hormone, insulin, and interferon α-2 have declined over the years due to improved downstream processing and formulation, reducing the level of impurities. There are studies showing the induction of antibodies by

oxidized protein which cross-reacted with the unmodified product [5] and host cell–derived endotoxin acting as an adjuvant. The probability of an immune response therefore increases with the level of impurities. Product modifications that are intended to enhance half-life potentially also increase the exposition of the protein to the immune system and may increase immunogenicity. In addition, the modification may reduce biological activity necessitating more protein for the same biological effect.

PEGylation (polyethylene glycol) is claimed to reduce the immunogenicity of therapeutic proteins by shielding. There is evidence that pegylation reduces the immunogenicity of nonhuman proteins such as bovine adenosine deamidase and asparginase. Whether pegylation also reduces the capacity of human proteins to break B-cell tolerance is less clear. There are reports of high immunogenicity of pegylated human proteins such as MDGF, but the immunogenicity of unpegylated MDGF products is unknown.

## Treatment Characteristics

Foreign proteins such as streptokinase and asparaginase often induce antibodies after a single injection. Breaking B-cell tolerance by human protein takes in general more than six months of chronic treatment. The route of administration influences the likelihood of an antibody response independent of the mechanism of induction. The probability of an immune response is highest with subcutaneous administration, less probable after intramuscular administration, and intravenous administration is the least immunogenic route. There are no studies comparing parenteral and nonparenteral routes of administration. However, intranasal and pulmonary administration of therapeutic proteins may induce an immune response.

## Patient Characteristics

Gender, age, and ethnic background have all been reported to influence the incidence of antibody response to specific therapeutic proteins. However, the only patient characteristic that has consistently been identified for a number of different products is the disease from which the patients suffer. Cancer patients are less likely to produce antibodies to therapeutic protein than other patients. The most widely accepted explanation for this difference is the immune-compromised state of cancer patients, both by the disease as by anticancer treatment. Also, the median survival of patients on treatment by therapeutic proteins may be too short to develop an antibody response. In any case, cancer reduces considerably the probability of an antibody response to a protein. As the experience in cancer patients shows, immune suppressive therapy reduces the probability to develop an immune response to proteins. In addition, immune-suppressive drugs such as methotrexate are used in conjunction with monoclonal antibodies and other protein drugs to reduce the immune reactions.

## PREDICTION OF IMMUNOGENICITY IN ANIMALS

In principle, all therapeutic proteins are immunogenic in conventional laboratory animals, and their predictive value depends on the type of proteins [6]. The immune reaction in animals to biopharmaceuticals of microbial or plant origin is comparable to humans, as they are comparably foreign for all mammalian species. Animal studies in which the reduction of immunogenicity is evaluated therefore have a high degree of predictability for immunogenicity in humans.

The development of antibodies has been observed regularly in preclinical studies in animals of biopharmaceuticals homologous to human proteins. Being considered a normal reaction to a foreign protein, it has led to the generally held assumption that immunogenicity testing and, in some cases, even preclinical testing in animals is irrelevant. However, not all antibodies interfere with the biological activity of a biopharmaceutical. And if there is a biological or clinical effect, these may help to identify the possible sequelae of immunogenicity, as has been shown with human epoetin in dogs. In the canine model human epoetin is immunogenic and it induces antibodies that neutralize the native canine epoetin, leading to pure red cell aplasia. This severe complication of antibodies to epoetin was later confirmed in humans.

Also, antibody-positive animals may provide sera for the development and validation of antibody assays; and the evaluation of an antibody response in animals is important to evaluate the safety and pharmacokinetic data in conventional laboratory animals. Nonhuman primates have been advocated as better models to predict the immunogenicity of human proteins because of a high sequence homology between the product and the monkey native molecule to which the animal is immune tolerant. Immunogenicity studies in nonhuman primates have, however, also shown mixed results. Products with a high immunogenicity in monkeys sometimes do not induce antibodies in human patients. The opposite has also been observed, although these studies may have been too limited in length of treatment or number of animals to be truly predictive. A good example of the possible use of monkeys was a study to determine the immunogenicity of different human growth hormone (hGH) preparations using a hyper-immunization protocol, including the use of adjuvant to provide a worst-case scenario of immunogenicity [7]. The monkeys were treated with cadaver-derived methionyl-hGH and natural sequence hGH. The antibody response was 81%, 69%, and 5 to 23%, respectively, which reflects the relative immunogenicity of these preparations in human patients. So in this example, rhesus monkeys predict relative immunogenicity.

Also, the immunogenicity of lys-pro biosynthetic human insulin was compared with the immunogenicity of porcine insulin and native-sequence insulin in rhesus monkeys. Neither of these proved to induce antibodies. With tissue plasminogen activators the immunogenicity in nonhuman primates was reported by the same group to reflect the immunogenicity in patients. Rhesus monkeys (*Macaca mulatta*) and cynomolgus monkeys (*M. fascicularis*) were

used to test antibody response to EPO/GM-CSF hybrids. Two of the three constructs tested produced high levels of neutralizing antibodies. In the rhesus monkeys these hybrids caused severe anemia. In cynomolgus monkeys no effect on hematological parameters was found, indicating lack of cross-reactivity of the antibodies with the native cynomolgus erythropoietin. There are also reports on immunogenicity of products in monkeys such as IFN α B/D, diaspirin cross-linked hemoglobin, and IL-3, which did not induce antibodies in patients. So monkeys cannot be used as absolute predictors of immunogenicity in humans, and even the response within the macaque family seems to differ.

Theoretically, the best predictive model for immunogenicity of human proteins is the transgenic mouse. These animals are immune tolerant for the human protein they express. The caveats are that the wild-type mouse strain used for transgenesis should be able to produce antibodies to the protein and that the transgenic should show immune tolerance for the native molecule and may be differences in the processing of antigens and epitope recognition between mouse and humans. Mice, transgenic for human insulin, showed that immunogenicity to variant insulin molecules was dependent on the number of substitutions. Mice that were made transgenic for human tissue plasminogen activator variants with a single amino acid substitution proved to be immunogenic, showing the discriminatory potential of the model [8]. The transgenic approach proved useful in finding a reason for the increased immunogenicity caused by a specific formulation. In mice transgenic for interferon α-2 only the batches immunogenic in patients produced antibodies [9]. The presence of aggregates and oxidized proteins proved the main cause of immunogenicity in the transgenic animals as in patients. In mice transgenic for hGH the immunogenicity of hGH encapsulated in microspheres for sustained release was tested and no enhanced immunogenicity was observed. We have used the transgenic mouse models to study the product characteristics capable of breaking tolerance. In these models, aggregates were shown to be the major factor. These models, however, have been used by us and others mainly in a yes-or-no fashion to study factors such as aggregates and sequence variations. To find subtle differences that may exist between products and before these models can be used to fully predict the immunogenic potential of human therapeutic proteins, much more validation is necessary. With no models yet available with sufficient predictive power, clinical studies are the only sure way to establish the induction of antibodies by therapeutic proteins.

## ASSAYS FOR ANTIBODIES

A cellular immune response to therapeutic proteins has never been established. Also, the biological and clinical consequences of an immune response to these products have always been associated with the presence of antibodies. So, by definition, a positive assay for antibodies is the biomarker for the immunogenicity of proteins. The lack of standardized assays and international

reference sera presents a major problem in assessing immunogenicity. It makes a comparison of antibody data generated by different laboratories impossible; comparisons of products based on published data (e.g., using information on package inserts) are also meaningless.

Recently, excellent reviews have been published regarding the development and validation of the various assay formats for antibodies to therapeutic proteins. There are two principles for the testing of antibodies: assays that monitor binding of antibody to the drug (EIA, RIA, BIAcore), or (neutralizing) bioassays. These assays are used in combination: a sensitive binding assay to identify all antibody-containing samples is often more practical, as bioassays are usually more difficult and time consuming. If a native molecule is modified (e.g., pegylated or truncated) to obtain a new product with different pharmacological characteristics, both the "parent" and the new molecule should be used as capture antigens for antibody assays.

A definition for the negative cutoff must be included in the validation process of this assay and is often based on the 5% false-positive rate. Such an analytical cutoff per se is not predictive of biological or clinical effect but rather, indicative of the technical limitations of the assay. And because the cutoff is set to include a relatively high number of false positives, all initial positive sera should be confirmed either by another binding assay or by a displacement assay.

The confirmed positive samples should be tested in a bioassay for neutralizing antibodies, which correlate with a potential in vivo effect in patients, as these antibodies are usually neutralizing because they interfere with receptor binding. A confirmatory step for neutralizing antibodies is not necessary because these antibodies are a subset of binding antibodies. In some cases it may be important to show the neutralization to be caused by antibodies if the presence of other inhibitory factors, such as a soluble receptor, has to be excluded. Further characterization of the neutralizing antibody response may follow, such as isotype, affinity, and specificity assays.

A positive or negative answer from the assays is not sufficient; development of antibodies is a dynamic process, and therefore the course of antibody development (kinetics) must be plotted quantitatively over time. Usually, persisting titers of neutralizing antibodies correlate with some biological effect. An analysis of the biological effect based on incidence may also be misleading. Akin to population kinetics in pharmacology, a method that compares relative immunogenicity in patient groups as "mean population antibody titers," taking into account both incidence and titers of neutralizing antibodies, has also been found more useful than a percentage of seroconversions for the purpose of comparing two products.

## CONSEQUENCES OF ANTIBODIES TO THERAPEUTIC PROTEINS

In many cases the presence of antibodies is not associated with biological or clinical consequences. The effects that antibodies may induce depend on their

level and affinity and can be the result of antigen–antibody reaction in general or of the specific interaction. Severe general immune reactions as anaphylaxis associated with the use of animal antisera have become rare because the purity of the products increased substantially. Delayed-type infusion-like reactions resembling serum sickness are more common, especially with monoclonal antibodies and other proteins administered in relative large amounts and the formation of immune complexes. Patients with a slow but steadily increasing antibody titer are reported to show more infusion-like reactions than patients with a short temporary response.

The consequences of the specific interaction between protein drugs is dependent on the affinity of the antibody translating in binding and/or neutralizing capacity. Binding antibodies may influence the pharmacokinetic behavior of the product, and both increases and reductions of half-life have been reported, resulting in enhancement or reduction in activity. Persisting levels of neutralizing antibodies in general result in a loss of activity of the protein drug. In some cases the loss of efficacy can easily be monitored by the increase of disease activity. For example, in interferon alpha treatment of hepatitis C, viral activity can be monitored by transaminase activity. Loss of efficacy is correlated directly by increased viral activity and increase in transaminase levels.

In the case of interferon beta treatment of multiple sclerosis the loss of efficacy is much more difficult to measure because the mode of action of the therapeutic protein is not known and the disease progress is unpredictable and difficult to monitor. The reduction of Mx induction which is specific for interferon activity has been used successfully to evaluate the biological effect of antibodies to interferon beta. The adverse effects of therapeutic proteins are in general the result of an exaggerated pharmacodynamic effect. So the loss of side effects may also be the result of the induction of antibodies and may be the first sign of immunogenicity. For example, in patients treated with interferon the loss of flulike symptoms is associated with the appearance of antibodies. Because by definition neutralizing antibodies interact with ligand–receptor interaction, they will inhibit the efficacy of all products in the same class with serious consequences for patients if there is no alternative treatment. The most dramatic side effects occur if the neutralizing antibodies cross-react with an endogenous factor with an essential biological function. This had been described for antibodies induced by epoetin alpha [10] and megakaryocyte growth and differentiation factor (MGDF), which led, respectively, to life-threatening anemia and thrombocytopenia, sometimes lasting for more than a year.

## Skin Reactions

Skin reactions are a common side effect of therapeutic proteins, and some of these reactions are associated with an immunogenic response. But can these skin reactions be used as a marker for the immunogenicity of therapeutic

proteins? The hypersensitivity reactions are classified as type I, II, III, and IV reactions. The type I reaction is IgE mediated. The type II reactions are caused by activated T-killer cells and macrophages and complement activation. The type III hypersensitivity reaction is caused by the disposition of immune complexes [11]. Type IV is T-cell mediated.

Type I hypersensitivity or IgE-mediated allergies are very rare, and most are related to the excipients present in formulation rather than the protein drug products. IgE-mediated reactions against human insulin have been reported, although is less common than with pork or beef insulin [12]. Theoretically, the type II hypersensitivity skin reaction may be a symptom of the immunogenicity of therapeutic proteins. During a type II hypersensitivity reaction, antibodies activate T-killer cells, macrophages, or complement factors to induce an immune response. However, the antibodies produced by most therapeutic proteins as a consequence of breaking B-cell tolerance and T-cells play only a minor role, if any.

TNF inhibitors such as etanercept cause injection-site reactions by a T-cell-mediated delayed-type hypersensitivity reaction. Antibodies against etanercept have been shown not to be correlated to adverse events. Skin reactions probably are a class effect of TNF inhibitors. Blockade of TNF can stimulate certain forms of autoimmunity by increasing T-cell reactivity to microbial and self-antigens [13].

The skin reactions that are part of the type III hypersensitivity reaction caused by the local disposition of immune complexes are seen after treatment with monoclonal antibodies, which are used in relative high and repeated doses. These immune complexes may lead to anaphylactoid reactions and serum sickness–like symptoms. Skin reactions such as urticaria and rashes are common symptoms of this complication [14]. Monoclonal antibodies may also lead to local reactions at the injection site. However, as shown in Table 2, there is no relation between immunogenicity and local skin reactions. So these local reactions cannot be used as an early marker for more serious symptoms of immunogenicity.

Some skin reactions seen after treatment with therapeutic proteins are the result of their pharmacodynamics: for example, the epidermal growth factor

**TABLE 2 Relation Between Local Skin Reactions and Immunogenicity of Monoclonal Antibodies**[a]

| | INN | Incidence of Antibodies (%) | Incidence of Local Skin Reactions (%) |
|---|---|---|---|
| Humira | adalimumab | 12 | 20 |
| Remicade | infliximab | 24 | 0 |
| Xolair | omalizumab | 0 | 45 |
| Mabthera | rituximab | 1 | >1 |

[a]Based on SPCs.

receptor (EGFR) inhibitors and beta interferon. EGFR plays a key role in normal skin function; thus, it is very likely that the rash and other skin reactions during therapy with EGFR inhibitors are caused by the inhibition of EGFR [14,15]. Interferon beta is known to induce high levels of neutralizing antibodies, but it seems that the adverse effects and skin reactions that occur during the first months of treatment have already disappeared when patients develop antibodies. Most probably, these adverse effects are a direct pharmacodynamic effect of interferon. Indeed, patients with neutralizing antibodies have a smaller risk of adverse events such as injection site reactions than do patients without [16,17]. So both local skin reactions at the site of injection and generalized reactions can be seen after the use of therapeutic proteins. These skin reactions can have different causes and cannot be used as biomarkers for immunogenicity.

## BIOMARKERS FOR THE IMMUNOGENICITY OF THERAPEUTIC PROTEINS

Two classes of biomarkers are used to indicate the clinical consequences of immunogenicity of therapeutic proteins:

1. *General:* persisting levels of neutralizing antibodies
2. *Specific:* loss of activity of endogenous homolog; increase in specific disease marker; decrease in efficiency marker

Biomarkers are also used to indicate the loss of efficiency of therapeutic proteins by antibodies:

1. *Monoclonal antibodies:* increase in side effects
2. *Other therapeutic proteins:* loss of side effects

Structural properties are the main primary factors of the induction of antibodies [18]. Therapeutic proteins of nonhuman origin will induce antibodies in the majority of patients after a limited number of applications. The degree of nonself and the presence of T-cell epitopes and the relative lack of immune tolerance are predictors of the antibody response.

Human homologs are less likely to be immunogenic. The best structural predictor of breaking tolerance is the presence of aggregates. The only animal model available for this type of immunogenicity is immune-tolerant transgenic mice. Induction of antibodies to human proteins usually occurs only after prolonged exposure. Independent of whether the protein is self or nonself, the possible immune modulating effect of the therapeutic protein, concomitant immune suppressive therapy, and the immune status of the patients are important predictors of an antibody response.

Antibody formation is by definition the marker for the immunogenicity of therapeutic proteins. The role of the cellular immunity is largely unknown and may be absent in the case of breaking B-cell tolerance. The occurrence of clinical consequences is in the majority of cases associated with relative high and persisting levels of neutralizing antibodies. In some cases the occurrence of neutralizing antibodies is preceded by binding antibodies, which may interfere with the pharmacokinetics of the proteins.

As discussed extensively, skin reactions cannot be seen as signs of the immunogenicity of proteins. Often, the loss of efficacy by neutralizing antibodies is difficult to assess because the diseases involved are chronic diseases with an unpredictable development and the proteins have only a limited effect. In these cases surrogate markers for efficacy may be monitored. Also, the effect on the side effects may be used as a marker. If the side effects are caused by the pharmacodynamic effect of the protein drugs, the loss of side effects is indicative of the development of neutralizing antibodies. If the side effect is the result of immune complexes, their appearance is associated with the induction of antibodies.

# NEW MARKERS OF KIDNEY INJURY

Sven A. Beushausen, Ph.D.
*Pfizer Global Research and Development, Chesterfield, Missouri*

## INTRODUCTION

The current biomarker standards for assessing acute kidney injury (AKI), caused by disease or as a consequence of drug-induced toxicity, include blood urea nitrogen (BUN) and serum creatinine (SC). Retention of either marker in the blood is indicative of impedance in the glomerular filtration rate (GFR), which if left untreated could escalate to serious kidney injury through loss of function and ultimately, death. Although the colorimetric assays developed for SC and BUN are relatively quick, seconds as compared to hours for antibody-based analysis platforms like enzyme-linked immunosorbent assay (ELISA), they are poor *predictors* of kidney injury because they both suffer from a lack of sensitivity and specificity. For example, SC concentration is greatly influenced by other nonrenal factors, including gender, age, muscle mass, race, drugs, and protein intake [1]. Consequently, increases in BUN and SC levels *report* out injury only after serious kidney damage has occurred. These shortcomings rather limit their clinical utility to patients who are at risk of developing drug-induced AKI or where instances of AKI have already been established, require frequent monitoring, and time to treatment is critical.

Renal failure or AKI is often a direct consequence of disease, can result from complications associated with disease or postsurgical trauma like sepsis,

**TABLE 1 Common Medications Associated with Acute Renal Injury**[a]

| Pathoetiology | Medication | Clinical Findings | Treatment |
|---|---|---|---|
| Prerenal injury | Diuretics, NSAIDs, ACE inhibitors, ciclosporin, tacrolimus, radiocontrast media, interleukin-2, vasodilators (hydralazine, calcium-channel blockers, minoxidil, diazoxide) | Benign urine sediment, FENa < 1%, UOsm > 500 | Suspend or discontinue medication, volume replacement as clinically indicated |
| Intrinsic renal injury<br>Vascular effects<br>Thrombotic microangiopathy | Ciclosporin, tacrolimus, mitomycin C, conjugated estrogens, quinine, 5-fluorouracil, ticlopidine, clopidogrel, interferon, valaciclovir, gemcitabine, bleomycin | Fever, microangiopathic, hemolytic anemia, thrombocytopenia | Discontinue medication, supportive care, plasmapheresis if indicated |
| Cholesterol emboli | Heparin, warfarin, streptokinase | Fever, microangiopathic, hemolytic anemia, thrombocytopenia | Discontinue medication, supportive care, plasmapheresis if indicated |
| Tubular toxicity | Aminoglycosides, radiocontrast media, cisplatin, nedaplatin, methoxyflurane, outdated tetracycline, amphotericin B, cephaloridine, streptozocin, tacrolimus, carbamazepine, mithramycin, quinolones, foscarnet, pentamidine, intravenous gammaglobulin, fosfamide, zoledronate, cidofovir,adefovir,tenofovir, mannitol, dextran, hydroxyethylstarch | FENa > 2%, UOsm < 350 urinary sediment with granular casts, tubular epithelial cells | Drug discontinuation, supportive care |

| | | | |
|---|---|---|---|
| Rhabdomyolysis | Lovastatin, ethanol, codeine, barbiturates, diazepam | Elevated CPK, ATN urine sediment | Drug discontinuation, supportive care |
| Severe hemolysis | Quinine, quinidine, sulfonamides, hydralazine, triamterene, nitrofurantoin, mephenytoin | High LDH, decreased hemoglobin | Drug discontinuation, supportive care |
| Immune-mediated interstitial inflammation | Penicillin, methicillin ampicillin, rifampin, sulfonamides, thiazides, cimetidine, phenytoin, allopurinol, cephalosporins, cytosine arabinoside, furosemide, interferon, NSAIDs, ciprofloxacin, clarithromycin, telithromycin, rofecoxib, pantoprazole, omeprazole, atazanavir | Fever, rash, eosinophilia, urine sediment showing pyuria, white cell casts, eosinophiluria | Discontinue medication, supportive care |
| Glomerulopathy | Gold, penicillamine, captopril, NSAIDs, lithium, mefenamate, fenoprofen, mercury, interferon-α, pamidronate, fenclofenac, tolmetin, foscarnet | Edema, moderate to severe proteinuria, red blood cells, red blood cell casts possible | Discontinue medication, supportive care |
| Obstruction Intratubular: (crystalluria and/or renal lithiasis) | Aciclovir, methotrexate, sulfanilamide, triamterene, indinavir, foscarnet, ganciclovir | Sediment can be benign with severe obstruction, ATN might be observed | Discontinue medication, supportive care |
| Ureteral (secondary to retroperitoneal fibrosis) | Methysergide, ergotamine, dihydroergotamine, methyldopa, pindolol, hydralazine, atenolol | Benign urine sediment, hydronephrosis on ultrasound | Discontinue medication, decompress ureteral obstruction by intrarenal stenting or percutaneous nephrostomy |

or is produced by drug-induced nephrotoxicity. Drug-induced renal injury is of great concern to physicians. Knowledge of toxicities associated with U.S. Food and Drug Administration (FDA)-approved compounds helps to guide product selection in an effort to manage risk and maximize patient safety. Drug-induced nephrotoxicity is of even greater concern to the pharmaceutical industry, where patient safety is the principal driver in the need to discover safer and more efficacious drugs. Because BUN and SC are such insensitive predictors of early kidney injury, many instances of subtle renal damage caused by drugs may go unrecognized. Consequently, true estimates for drug-induced nephrotoxicity are likely to be far lower than previously realized. For example, studies have indicated that the incidence of acute tubular necrosis or acute interstitial nephritis due to medication has been estimated to be as high as 18.6% [2]. In addition, renal injury attributed to treatment with aminoglycosides has been reported to approach 36% [3,4]. Not surprisingly, many common drugs have been associated with renal injury that cause site-specific damage (Table 1).

Fortunately, most instances of drug-induced nephrotoxicity are reversible if discovered early and medication is discontinued. Collectively, the combined shortcomings of BUN and SC as *predictors* of nephrotoxicity and the propensity for many classes of medicines to cause drug-induced nephrotoxicity underscore the urgent need for the development and qualification of more sensitive and specific biomarkers. The benefits such tools will provide include predictive value and earlier diagnosis of drug-induced kidney injury before changes in renal function or clinical manifestations of AKI are evident. More important, biomarkers of nephrotoxicity with increased sensitivity and specificity will be invaluable to drug development both preclinically and clinically. Preclinically, new biomarkers will aid in the development of safer drugs having fewer liabilities with an ultimate goal to considerably lower or even possibly eliminate drug-induced nephrotoxicity. Clinically, the biomarkers will be used to monitor potential nephrotoxic effects due to therapeutic intervention or the potential for new drugs to cause renal toxicity in phase I to III clinical trials.

## NEW PRECLINICAL BIOMARKERS OF NEPHROTOXICIY

In recent years, two consortia led by the nonprofit organizations ILSI-HESI (International Life Sciences Institute, Health and Environmental Sciences Institute, http://www.hesiglobal.org) and C-Path (Critical Path Institute, http://www.c-path.org) aligned with leaders in academia, industry, and the FDA with a mission to evaluate the potential utility of newly identified biomarkers of nephrotoxicity for use in preclinical safety studies and to develop a process for the acceptance of the new biomarkers in support of safety data accompanying new regulatory submissions. Several criteria for the evaluation and development of new biomarkers of nephrotoxicity were considered, including:

**TABLE 2 Biomarkers of Renal Injury by Region of Specificity, Onset, Platform, and Application**

| Biomarker | Injury Related to: | Onset | Platforms | Application |
|---|---|---|---|---|
| $\beta_2$-Microglobulin | Proximal tubular injury | Early | Luminex, ELISA | Mouse, rat, human, chicken, turkey |
| Clusterin | Tubular epithelial cells | Early | Luminex, ELISA | Mouse, rat, dog, monkey, human |
| Cystatin-C | Tubular dysfunction | Late | Luminex, ELISA | Mouse, rat, human |
| GSTα | Proximal tubular injury | Early | Luminex, ELISA | Mouse, rat, human |
| GST Yb1 | Distal tubule | Early | Luminex, ELISA | |
| KIM-1 | General kidney injury and disease | Early | Luminex, ELISA | Zebrafish, mouse, rat, dog, monkey, human |
| Microalbumin | Proximal tubular injury | Early | Luminex, ELISA | Mouse, rat, dog, monkey, human |
| Osteopontin | Tubulointerstitial fibrosis | Late | Luminex, ELISA | Mouse, rat, monkey, human |
| NGAL | Proximal tubular injury | Early | Luminex, ELISA | Mouse, rat, human |
| RPA-1 | Renal papilla and collecting ducts | Early | ELISA | Rat |

*Source:* Adapted from ref. 5.

- A preference for noninvasive sample collection.
- New biomarkers developed for preclinical use should optimally be translated to the clinic.
- Assays for new biomarkers should be robust and kits readily available for testing.
- Assays should be multiplexed to minimize cost and expedite sample analysis.
- Biomarkers should ideally predict or report out site-specific injury.
- Biomarkers must be more sensitive and specific of kidney injury than existing standards.
- Biomarkers should be predictive (prodromal) of kidney injury in the absence of histopathology.

The preference for noninvasive sample collection made urine the obvious choice of biofluid. Urine has proven to be a fertile substrate for the discovery of promising new biomarkers for the early detection of nephrotoxicity [5]. A number of these markers have been selected for further development and

qualification by the ILSI-HESI and C-Path Nephrotoxicity Working Groups in both preclinical and clinical settings, with the exception of RPA-1 and GST Yb1 (Biotrin), which are markers developed specifically for the analysis of kidney effects in rats (Table 2). The utility and limitations of each marker used in the context of early and site-specific detection are discussed below.

## $\beta_2$-Microglobulin

Human $\beta_2$-microglobulin ($\beta_2$M) was isolated and characterized in 1968 [6]. $\beta_2$M was identified as a small 11,815-Da protein found on the surface of human cells expressing the major histocompatibility class I molecule [7]. $\beta_2$M is shed into the circulation as a monomer, from which it is normally filtered by the glomerulus and subsequently reabsorbed and metabolized within proximal tubular cells [8]. Twenty-five years ago, serum $\beta_2$M was advocated for use as an index of renal function because of an observed proportional increase in serum $\beta_2$M levels in response to decreased renal function [9]. It has since been abandoned due to a number of factors complicating the interpretation of the findings. More recently, increased levels of intact urinary $\beta_2$M have been directly linked to impairment of tubular uptake. Additional work in rats and humans has demonstrated that increased urinary levels of $\beta_2$M can be used as a marker for proximal tubular function when $\beta_2$M production and glomerular filtration are normal in a setting of minimal proteinuria [10–13].

Urinary $\beta_2$M has been shown to be superior to *N*-acetyl-β-glucosaminidase as a marker in predicting prognosis in idiopathic membranous neuropathy [14]. In this context $\beta_2$M can be used to monitor and avoid unnecessary immunosuppressive therapy following renal transplantation. $\beta_2$M is being considered for evaluation as an early predictor of proximal tubular injury in preclinical models of drug-induced nephrotoxicity. Although easily detected in urine, there are several factors that may limit its value as a biomarker. For example, $\beta_2$M is readily degraded by proteolytic enzymes at room temperature and also degrades rapidly in an acidic environment at or below pH < 6.0 [15]. Therefore, great care must be taken to collect urine in an ice-cold, adequately buffered environment with the addition of stabilizers to preserve $\beta_2$M levels during the period of collection and in storage. It is unlikely that $\beta_2$M will be used as a stand-alone marker to predict or report proximal tubule injury preclinically or in the clinic. Rather, it is likely to be used in conjunction with other proximal tubule markers to support such a finding. A brief survey for commercially available antibodies used to detect $\beta_2$M indicates that most are species specific (http://www.abcam.com). Instances of cross-reactivity were noted for specific reagents between human and pig, chicken and turkey, and human and other primates. A single monoclonal reagent is reported to have cross-reactivity with bovine, chicken, rabbit, and mouse, and none were listed that specifically recognized dog $\beta_2$M. Because both commonly used preclinical species rat and dog $\beta_2$M proteins share only 69.7% and 66.7% amino acid identity with the human protein (http://www.expasy.org), it would be prudent to develop and

characterize antibody reagents specific to each species and cross-reacting antisera to specific amino acid sequences shared by all three proteins.

## Clusterin

Clusterin is a highly glycosylated and sulfated secreted glycoprotein first isolated from ram rete testes fluid in 1983 [16]. It was named clusterin because of its ability to elicit clustering of Sertoli cells in vitro [17]. Clusterin is found primarily in the epithelial cells of most organs. Tissues with the highest levels of clusterin include testis, epididymus, liver, stomach, and brain. Metabolic and cell-specific functions assigned to clusterin include sperm maturation, cell transformation, complement regulation, lipid transport, secretion, apoptosis, and metastasis [18]. Clusterin is also known by a number of synonyms as a consequence of having been identified simultaneously in many parallel lines of inquiry. Names include glycoprotein III (GPIII), sulfated glycoprotein-2 (SG-2), apolipoprotein J (apo J), testosterone-repressed message-2 (TRPM-2), complement associated protein SP-40, 40, and complement cytolysis inhibitor protein (see Table 1). Clusterin has been cloned from a number of species, including the rat [19]. The human homolog is 449 amino acids in length, coding for a protein with a molecular weight of 52,495 Da [20]. However, due to extensive posttranslational modification, the protein migrates to an apparent molecular weight of 70 to 80 kDa following sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). Amino acid identity between species is moderate. Human clusterin shares 70.3%, 76.6%, 71.7%, and 77% with the bovine, mouse, pig, and rat homologs, respectively (http://www.expasy.org).

Clusterin is a heterodimer comprised of an α and a β subunit, each having an apparent mass of 40 kDa by SDS-PAGE. The subunits result from the proteolytic cleavage of the translated polypeptide at amino acid positions 23 and 277. This eliminates the leader sequence and produces the mature 205-amino acid β subunit and the remaining 221-amino acid α subunit. The α and β subunits are held together by five sulfhydryl bonds afforded by cysteine residues clustered within each of the subunits [21]. In addition, each subunit has three N-linked carbohydrates that are also heavily sulfated, giving rise to the higher apparent molecular weight observed following SDS-PAGE. Considerable evidence has been provided suggesting that clusterin plays an important role in development. For example, clusterin mRNA expression has been observed at 12.5 days' postgestation in mice, where it is present in all germ cell layers [22]. Furthermore, stage-specific variations of the transcript have been observed, as have changes in specific localization during development. Similarly, changes in the developmental expression of clusterin in kidney, lung, and nervous system have also been reported [23]. These observations suggest that clusterin might play a role in tissue remodeling.

In the developing murine kidney, clusterin is expressed in the tubular epithelium and later in development is diminished as tubular maturation progresses [24]. Interestingly, clusterin is observed in newly formed tubules

but appears to be absent in glomeruli. Of interest to many investigators of renal function is the reemergence of clusterin observed following induction of a variety of kidney diseases and drug-induced renal injury. Clusterin induction has been observed following ureteral obstruction [25] and ischemia reperfusion injury [26]. Elevations in the levels of clusterin have also been observed in the peri-infarct region following subtotal nephrectomy [27] and in animal models of hereditary polycystic kidney disease [28]. Marked increases of clusterin released in urine have also been recorded in animal models of aminoglycoside-induced nephrotoxicity [29–31].

Authors have opined that clusterin functions in either a protective role by scavenging cell debris or may play a role in the process of tissue remodeling following cellular injury based on these observations. Collectively, the body of work linking elevated levels of urinary clusterin to kidney damage has suggested that measurement of urinary clusterin may be useful as a marker of renal tubular injury. Indeed, an early study comparing urinary levels of clusterin against *N*-acetyl-β-glucosaminidase (NAG) following chronic administration of gentamicin over a two-month period demonstrated that while the urinary levels of both proteins rose rapidly, peaked, and then declined, clusterin levels remained significantly higher than control values over the duration of the experiment. By contrast, NAG levels dropped to within control values within 10 days of treatment even though evidence of tubulointerstitial disease persisted [30]. More recent work examining the levels of urinary clusterin in the autosomal-dominant polycystic kidney disease (cy/+) rat model compared to the FHH rat model of focal segmental glomerulosclerosis following bilateral renal ischemia demonstrated that clusterin levels correlated with the severity of tubular damage and suggested use as a marker for differentiating between tubular and glomerular damage [32]. Although the value of clusterin as an early marker of tubular epithelial injury has not yet been established clinically, preclinical findings suggest that it is an ideal candidate for translation to the clinic as an early marker of nephrotoxicity.

## Cystatin-C

Cystatin C (Cys-C) is a 13-kDa nonglycosylated protein belonging to the superfamily of cysteine protease inhibitors [33]. Cys-C is produced by all nucleated cells and, unlike SC, is unaffected by muscle mass. Serum Cys-C was suggested to be closer to the "ideal" biomarker reporting GFR because although freely filtered by the glomerulus, it is not secreted. Instead, Cys-C is adsorbed by tubular epithelial cells, where it is catabolized and is not returned to the bloodstream, thus obviating the need to calculate urinary Cys-C to measure GFR [34]. Several studies have been designed to examine the usefulness of serum Cys-C as a measure or biomarker of GFR [35]. In one such study, serum Cys-C was shown to be a useful biomarker of acute renal failure and could be detected one to two days prior to the elevation in levels of SC, the accepted clinical diagnosis of AKI [36]. Although earlier in detection than

SC, serum Cys-C levels were not predictive of kidney disease and, like SC, reported out kidney injury long after serious damage had occurred. In another study, investigators monitored and compared the levels of serum Cys-C and urinary Cys-C in patients following cardiothoracic surgery with and without complicating AKI [37]. The results clearly demonstrated that while plasma Cys-C was not a useful predictor of AKI, early and persistent increases in urinary Cys-C correlated with the development and severity of AKI. Another interesting but unexplained observation in this study was that women had significantly higher postoperative levels of urinary Cys-C than did men even though preoperative Cys-C levels were similar. These data have prompted groups like ILSI-HESI and C-Path to examine the utility of urinary Cys-C as a preclinical biomarker of drug-induced renal injury in the hope that elevated levels of Cys-C can be detected in urine prior to the emergence of overt tubular dysfunction.

## Glutathione S-Transferases

The glutathione S-transferases (GSTs) form a family of homo-and heterodimeric detoxifying enzymes [38] identified originally as a group of soluble liver proteins that play a major role in the detoxification of electrophilic compounds [39]. They have since been shown to be products of gene superfamilies [40] and are classified into alpha, mu, pi, and theta subfamilies based on sequence identity and other common properties [41]. Tissue distribution and levels of GST isoform expression has been determined by immunohistochemical localization [42], isoform-specific peptide antibody Western blotting, and mass spectrometry [40]. Analysis of GST subunit diversity and tissue distribution using peptide-specific antisera has shown GST μ isoforms to be the most widely distributed class of GSTs, with expression evident in brain, pituitary, heart, lung, adrenal gland, kidney, testis, liver, and pancreas, with the highest levels of GST μ1 observed in adrenals, testis, and liver. Isoforms of the GSTα subfamily, also known by the synonyms glutathione S-transferase-1, glutathione S-transferase Ya-1, GST Ya1, ligandin, GST 1a-1a, GST B, GST 1-1, and GST A1-1 (http://www.expasy.org/uniprot/P00502), are more limited in distribution, with highest levels of expression observed in hepatocytes and proximal tubular cells of the kidney [42].

Indeed, proximal tubular GSTα levels have been reported to approximate 2% of total cytosolic protein following exposure to xenobiotics or renal toxins [43]. In the Rowe study [40], GSTα was found to be rather evenly distributed between adrenals, kidney, and pancreas, with highest levels observed in liver, whereas isoforms of the GSTπ subclass were expressed in brain, pituitary, heart, liver, kidney, and adrenals, with highest levels of expression observed in kidney. The high levels of expression and differential distribution of GST isoforms made them attractive candidates as biomarkers that could be used to indicate site-specific drug-induced nephrotoxicity. For example, development of a radioimmunoassay to quantify leakage of ligandin (GSTα)

into the urine as a measure of nephrotoxicity in the preclinical rat model was reported as early as 1979 [44]. Subsequent work described the development of a radioimmunoassay for the quantitation of GSTπ in the urine [45a] later used as an indicator of distal tubular damage in the human kidney [45b]. Additional work described the development of a multiplexed ELISA for the simultaneous quantitation of GSTα and GSTπ to discriminate between proximal and distal tubular injury, respectively [46].

In terms of sensitivity, a study examining the nephrotoxic effects of the sevoflurane degradation product, fluoromethyl-2,2-difluoro-1-(trifluoromethyl) vinyl ether, in rats showed urinary GSTα to be the most sensitive marker of mild proximal tubular damage compared to other urinary markers measured, including protein and glucose [47]. A second study in which four human volunteers were given sevoflurane demonstrated abnormalities in urinary glucose, albumin, GSTα, and GSTπ, while levels of BUN or SC were unaffected, suggesting that the GSTs were more sensitive markers of site-specific dug-induced nephrotoxicity [48]. Immunohistochemical staining of the rat kidney with antibodies to different GST isoforms has shown that GSTα subunits are expressed selectively in the proximal tubule, whereas GSTμ and π subnits are localized to the thin loop of Henle and proximal tubules, respectively [38]. An examination of the distribution of the rat GSTμ equivalent, GSTYb1, in the kidney indicates that it is localized to the distal tubules. Simultaneous measurement of urinary GSTα and GSTYb1 has been used to discriminate between drug-induced proximal and distal tubular injury (cited by Kilty et al. [49]). The high levels of GSTs in the kidney and site-specific localization of different GST classes in addition to increased sensitivity in detecting drug-induced nephrotoxicity in humans make them ideal candidates for the development and testing of preclinical markers that predict or report early signs of nephrotoxicity to support preclinical safety studies and subsequent compound development.

## Kidney Injury Molecule 1

Rat kidney injury molecule 1 (KIM-1) was discovered as part of an effort to identify genes implicated in kidney injury and repair [50] using the polymerase chain reaction (PCR) subtractive hybridization technique of representational difference analysis originally developed to look at differences in genomic DNA [51] but adapted to examine differences in mRNA expression [52]. Complementary DNA generated from poly(A+) mRNA purified from normal and 48-hour postischemic rat kidneys was amplified to generate driver and tester amplicons, respectively. The amplicons were used as templates to drive the subtractive hybridization process to generate designated differential products, three of which were ultimately gel purified and subcloned into the pUC18 cloning vector. Two of these constructs were used to screen λZapII cDNA libraries constructed from 48-hour postischemic rat kidneys. Isolation and purification of positively hybridizing plaques resulted in the recovery of a

2.5-kb clone that contained sequence information on all three designated differential products. A BLAST search of the NCBI database revealed that the rat KIM-1 sequence had limited (59.8%) amino acid homology to HAVcr-1, identified earlier as the monkey gene coding for the hepatitis A virus receptor protein [53]. The human homolog of KIM-1 was isolated by low-stringency screening of a human embryonic liver λgt10 cDNA library using the same probe that yielded the rat clones [50]. The plaque of one of two clones purified from this exercise was shown to code for a 334-amino acid protein sharing 43.8% identity and 59.1% similarity to the rat KIM-1 protein. Comparison to the human HAVcr protein [54] revealed 85.3% identity demonstrating a clear relationship between the two proteins.

Subsequent work has demonstrated that KIM-1 and HAVcr are synonyms for the same protein, also known as T-cell immunoglobulin and mucin domain–containing protein 1 (TIMD-1) and TIM-1. The TIMD proteins are all predicted to be type I membrane proteins that share a characteristic immunoglobulin V, mucin, transmembrane, and cytoplasmic domain structure [55]. It is not clear what the function of KIM-1 (TIMD-1) is, but it is believed that TIMD-1 is involved in the preferential stimulation of Th2 cells within the immune system [56]. In the rat, KIM-1 mRNA expression is highest in liver and barely detected in kidney [50]. KIM-1 mRNA and protein expression are dramatically up-regulated following ischemic injury. Immunohistochemical examination of kidney sections using a rat-specific KIM-1 antibody showed that KIM-1 is localized to regenerating proximal tubule epithelial cells. KIM-1 was proposed as a novel biomarker for human renal proximal tubule injury in a study that demonstrated that KIM-1 could be detected in the urine of patients with biopsy-proven acute tubular necrosis [57]. Human KIM-1 occurs as two splice variants that are identical with respect to the extracellular domains but differ at the carboxy termini and are differentially distributed throughout tissues [58]. Splice-variant KIM-1b is 25 amino acids longer than the originally identified KIM-1a and is found predominantly in human kidney.

Interestingly, cell lines expressing endogenous KIM-1 or recombinant KIM-1b constitutively shed KIM-1 into the culture medium, and shedding of KIM-1 could be inhibited with metalloprotease inhibitors, suggesting a mechanism for KIM-1 release into the urine following the regeneration of proximal tubule epithelial cells as a consequence of renal injury. Evidence supporting KIM-1's potential as a biomarker for general kidney injury and repair was clearly demonstrated in another paper describing the early detection of urinary KIM-1 protein in a rat model of drug-induced renal injury. In this study increases in KIM-1 were observed before significant increases in SC levels could be detected following injury with folic acid and prior to measurable levels of SC in the case of cisplatin-treated rats [59]. In later, more comprehensive studies examining the sensitivity and specificity of KIM-1 as an early biomarker of mechanically- [60] or drug-induced renal injury [61], KIM-1 was detected earlier than any of the routinely used biomarkers of renal injury,

including BUN, SC, urinary NAG, glycosuria, and proteinuria. Certainly, the weight of evidence described above supports the notion that KIM-1 is an excellent biomarker of AKI and drug-induced renal injury. The increasing availability of antibody-based reagents and platforms to rat and human KIM-1 proteins offer convenient and much needed tools for preclinical safety assessment of drug-induced renal toxicity and for aid in diagnosing or monitoring mild to severe renal injury in the clinic. Further work is required to determine if KIM-1 is a useful marker for long-term injury and whether it can be used in combination with other makers to determine site-specific kidney injury.

## Microalbumin

The examination of proteins excreted into urine provides useful information about renal function (reviewed in [62]). Tamm–Horsfall proteins that originate from renal tubular cells comprise the largest fraction of protein excreted in normal urine. The appearance of low-molecular-weight urinary proteins normally filtered through the basement membrane of the glomerulus, including insulin, parathormone, lysozyme, trypsinogen and $\beta_2$-microglobulin indicate some form of tubular damage [63]. The detection of higher-molecular-weight (40- to 150-kDa) urinary proteins not normally filtered by the glomerulus, including albumin, transferrin, IgG, caeruloplasmin, $\alpha$1-acid glycoprotein, and HDL, indicate compromised glomerular function [64]. Albumin is by far the most abundant protein constituent of proteinuria. Although gross increases in urinary albumin measured by the traditional dipstick method with a reference interval of 150 to 300 mg/mL have been used to indicate impairment of renal function, there are many instances of subclinical increases of urinary albumin within the defined reference interval that are predictive of disease [65–67].

The term *microalbuminuria* was coined to define this phenomenon, where such increases had value in predicting the onset of nephropathy in insulin-dependant diabetes mellitus [68]. The accepted reference interval defined for microalbuminuria is between 30 to 300 mg in 24 hours [69,70]. Because microalbuminuria appears to be a sensitive indicator of renal injury, there is a growing interest in the nephrotoxicity biomarker community to evaluate this marker in the context of an early biomarker predictive of drug-induced renal injury. Although microalbuminuria has traditionally been used in preclinical drug development to assess glomerular function there is growing evidence to suggest that albuminuria is a consequence of impairment of the proximal tubule retrieval pathway [71]. Evidence that microalbuminuria might provide value in diagnosing drug-induced nephrotoxicity was reported in four of 18 patients receiving cisplatin, ifosamide, and methotrextate to treat osteosarcoma [72]. Because microalbuminuria can be influenced by other factors unrelated to nephrotoxicity, including vigorous exercise, hematuria, urinary tract infection, and dehydration [5], it may have greater predictive value for renal

injury in the context of a panel of markers with increased sensitivity and site specificity. Indeed, further evaluation of microglobulin as an early biomarker of site-specific or general nephrotoxicity is required before qualification for preclinical and clinical use.

## Osteopontin

Osteopontin (OPN) is a 44-kDa highly phosphorylated secreted glycoprotein originally isolated from bone [73]. It is an extremely acidic protein with an isoelectric point of 4.37 (http://www.expasy.org/uniprot/P10451), made even more acidic through phosphorylation on a cluster of up to 28 serine residues [74]. Osteopontin is widely distributed among different tissues, including kidney, lung, liver, bladder, pancreas, and breast [75] as well as macrophages [76], activated T-cells [77], smooth muscle cells [78], and endothelial cells [79]. Evidence has been provided demonstrating that OPN functions as a calcium oxalate crystal formation inhibitor in cultured murine kidney cortical cells [80]. Immunohistochemical and in situ hybridization examination of the expression and distribution of OPN protein and mRNA in the rat kidney clearly demonstrated that levels are highest in the descending thin loop of Henle and cells of the papillary surface epithelium [81]. Uroprontin, first described as a relative of OPN was among the first examples of OPN isolation from human urine [82].

Although normally expressed in kidney, OPN expression can be induced under a variety of experimental pathologic conditions [83,84], including tubulointerstitial nephritis [85], cyclosporine-induced neuropathy [86], hydronephrosis as a consequence of unilateral ureteral ligation [87], renal ischemia [88], nephropathy induced by cisplatin, and crescentric glomeulonephritis [89]. Up-regulation of OPN has been reported in a number of animal models of renal injury, including drug-induced nephrotoxicity by puromycin, cylcoaporine, strptozotocin, phenylephrine, and gentamicin (reviewed in [90a]). In the rat, gentamicin-induced acute tubular necrosis model OPN levels were highest in regenerating proximal and distal tubules, leading the authors to conclude that OPN is related to the proliferation and regeneration of tubular epithelial cells following tubular damage [90b]. Although osteopontin has been proposed as a selective biomarker of breast cancer [91] and a useful clinical biomarker for the diagnosis of colon cancer [92], OPN shows great promise and requires further evaluation as a clinical biomarker for renal injury. Certainly, the high levels of OPN expression following chemically or physically induced renal damage coupled with the recent availability of antibody-based reagents to examine the levels of mouse, rat, and human urinary OPN provide ample opportunity to evaluate OPN as an early marker of AKI in the clinic and a predictive marker of drug-induced nephrotoxicity preclinically. Further planned work by the ILSI-HESI and C-Path groups hope to broaden our understanding regarding the utility of OPN in either capacity as an early predictor of renal injury.

## Neutrophil Gelatinase–Associated Lipocalin

Neutrophil gelatinase–associated lipocalin (NGAL) was first identified as the small molecular-weight glycoprotein component of human gelatinase affinity purified from the supernatant of phorbol myristate acetate stimulated human neutrophils. Human gelatinase purifies as a 135-kDa complex comprised of the 92-kDa gelatinase protein and the smaller 25-kDa NGAL [93]. NGAL has subsequently been shown to exist primarily in monomeric or dimeric form free of gelatinase. A BLAST search of the 178-amino acid NGAL protein yielded a high degree of similarity to the rat α2 microglobulin-related protein and mouse protein 24p3, suggesting that NGAL is a member of the lipocalin family. Lipocalins are characterized by the ability to bind small lipophilic substances and are thought to function as modulators of inflammation [94]. More recent work has shown that NGAL, also known as siderocalin, complexes with iron and iron-binding protein to promote or accelerate recovery from proximal tubular damage (reviewed in [95]). RNA dot blot analysis of 50 human tissues revealed that NGAL expression is highest in trachea and bone tissue, moderately expressed in stomach and lung with low levels of transcript expression in the remaining tissues examined, including kidney [94]. Because NGAL is a reasonably stable small-molecular-weight protein, it is readily excreted from the kidney and can be detected in urine.

NGAL was first proposed as a novel urinary biomarker for the early prediction of acute renal injury in rat and mouse models of acute renal failure induced by bilateral ischemia [96]. Increases in the levels of urinary NGAL were detected in the first hour of postischemic urine collection and shown to be related to dose and length of exposure to ischemia. In this study the authors reported NGAL to be more sensitive than either NAG or $\beta_2$M, underscoring its usefulness as an early predictor of acute renal injury. Furthermore, the authors proposed NGAL to be an earlier marker predictive of acute renal injury than KIM-1, since the latter reports injury within 24 hours of renal injury compared to 1 hour for NGAL. Marked up-regulation of NGAL expression was observed in proximal tubule cells within 3 hours of ischemia-induced damage, suggesting that NGAL might be involved in postdamage reepithelialization. Additional work demonstrated that NGAL expression was induced following mild ischemia in cultured human proximal tubule cells. This paper also addressed the utility of NGAL as an early predictor of drug-induced renal injury by detecting increased levels of NGAL in the urine of cisplatin-treated mice.

Adaptation of the NGAL assay to address utility and relevance in a clinical setting showed that both urinary and serum levels of NGAL were sensitive, specific, and highly predictive biomarkers of acute renal injury following cardiac surgery in children [97]. In this particular study, multivariate analysis showed urinary NGAL to be the most powerful predictor in children that developed acute renal injury. Measurable increases in urinary NGAL concentrations were recorded within 2 hours of cardiac bypass surgery, whereas

increases in SC levels were not observed until 1 to 3 days postsurgery. Other examples demonstrating the value of NGAL as a predictive biomarker of early renal injury include association of NGAL with severity of renal disease in proteineuric patients [98] and NGAL as an early predictor of renal disease resulting from contrast-induced nephropathy [99]. NGAL has been one of the most thoroughly studied new biomarkers predictive of AKI as a consequence of disease or surgical intervention, and to a lesser extent, drug-induced renal injury.

Sensitive and reliable antibody-based kits have been developed for a number of platforms in both humans and rodents (Table 2) and there is considerable interest in examining both the specificity and sensitivity of NGAL for acceptance as a fit-for-purpose predictive biomarker of drug-induced renal injury to support regulatory submissions. Certainly, because NGAL is such an early marker of renal injury, it will have to be assessed as a stand-alone marker of renal injury as well as in the context of a larger panel of markers that may help define site specific and degree of kidney injury.

## Renal Papillary Antigen 1

Renal papillary antigen 1 (RPA-1) is an uncharacterized antigen that is highly expressed in the collecting ducts of the rat papilla and can be detected at high levels in rat urine following exposure to compounds that induce renal papillary necrosis [100]. RPA-1 was identified by an $IgG_1$ monoclonal antibody, designated Pap X 5C10, that was generated in mice immunized with pooled fractions of a cleared lysate of homogenized rat papillary tissue following crude DEAE anion-exchange chromatography. Immunohistochemical analysis of rat papillae shows that RPA-I is localized to the epithelial cells lining the luminal side of the collecting ducts and to a lesser extent in cortical collecting ducts. A second publication described the adaptation of three rat papilla-specific monoclonal antibodies, including Pap X 5C10 (PapA1), to an ELISA assay to examine antigen excretion in rat urine following drug-induced injury to the papillae using 2-bromoethanamine, propyleneimine, indomethicin, or ipsapirone [101]. Of the three antibodies evaluated, PapA1 was the only antigen released into the urine of rats following exposure to each of the toxicants. The authors concluded that changes in the rat renal papilla caused by xenobiotics could be detected early by urinary analysis and monitored during follow-up studies. This study also clearly demonstrated that the Pap X 5C10, PapA1, RPA-1 antigen had the potential for use as a site-specific biomarker predictive of renal papillary necrosis. Indeed, the Pap X 5C10 monoclonal antibody was adapted for commercial use as an RPA-1 ELISA kit marketed specifically to predict or monitor site-specific renal injury in the rat [49].

The specificity and sensitivity of the rat reagent has generated a great deal of interest in developing an equivalent reagent for the detection of human papillary injury. Identification of the RPA-1 antigen remains elusive. Early biochemical characterization of the antigen identified it as a large-

molecular-weight protein (150 to 200 kDa) that could be separated into two molecular-weight species with isoelectric points of 7.2 and 7.3, respectively [100]. However, purification and subsequent protein identification of the antigen were extremely challenging. A recent attempt at the biochemical purification and identification of the RPA-1 antigen has been equally frustrating, with investigators providing some evidence that the antigen may be a large glycoprotein and suggesting that the carbohydrate moiety is the specific epitope recognized by the Pap X 5C10 monoclonal antibody [102]. This would be consistent with, and help to explain why, the rat reagent does not cross-react with a human antigen in the collecting ducts, as protein glycosylation of related proteins often differs dramatically between species, thereby precluding the likelihood of presenting identical epitopes. Nevertheless, continued efforts toward identifying a human RPA-1 antigen will provide investigators with a sorely needed clinical marker for the early detection of drug-induced renal papillary injury.

## SUMMARY

A considerable amount of effort has gone into identifying, characterizing, and developing new biomarkers of renal toxicity having greater sensitivity and specificity than the traditional markers, BUN and SC. The issue of sensitivity is a critical one, as the ideal biomarker would detect renal injury before damage is clinically evident or cannot be reversed. Such prodromal biomarkers would provide great predictive value to the pharmaceutical industry in preclinical drug development, where compounds could be modified or development terminated early in response to the nephrotoxicity observed. Even greater value could be realized in the clinic, where early signs of kidney injury resulting from surgical or therapeutic intervention could be addressed immediately before serious damage to the patient has occurred.

Several of the candidate markers described above, including $\beta_2$M, GST$\alpha$, microalbumin, KIM-1, and NGAL, have demonstrated great promise as early predictors of nephrotoxicity. Continued investigation should provide ample data from which to make a determination regarding the utility of these markers for preclinical and, ultimately, clinical use. The issue of biomarker specificity is also of great value because it provides information regarding where and to what extent injury is occurring. For example, increases in levels of SC and BUN inform us that serious kidney injury has occurred but does not reveal the precise nature of that injury, whereas the appearance of increased levels of $\beta_2$M, GST$\alpha$, microalbumin, and NGAL indicate some degree of proximal tubule injury. Similarly, RPA-1 reports injury to the papilla, clusterin indicates damage to tubular epithelial cells, and GSTYb1 is specific to distal tubular damage. Low-level increases of early markers warn the investigator or clinician that subclinical damage to the kidney is occurring and provides the necessary time to alter or terminate a course of treatment or development.

Monitoring toxicity is an important aspect of achieving a positive clinical outcome and increased safety in drug development. Incorporation of many or all of these markers into a panel tied to an appropriate platform allows for the simultaneous assessment of site-specific kidney injury with some understanding of the degree of damage. Several detection kits are commercially available for many of these new biomarkers of nephrotoxicity. For example, Biotrin International provides ELISA kits for the analysis of urinary GSTs and RPA-1, while Rules Based Medicine and Meso Scale Discovery offer panels of kidney biomarkers multiplexed onto antibody-based fluorescence or chemiluminescent platforms, respectively. As interest in new biomarkers of kidney injury continues to develop, so will the technology that supports them. Presently, all of the commercial reagents and kits supporting kidney biomarker detection are antibody-based. The greatest single limitation of such platforms is how well the reagents perform with respect to target identification, nonspecific protein interaction, and species cross reactivity. Although kits are standardized and come complete with internal controls, kit-to-kit and lab-to-lab variability can be high.

Another technology being developed for the purpose of quantifying biomarkers in complex mixtures such as biofluids is mass spectrometry–based multiple reaction monitoring. This technology requires the synthesis and qualification of small peptides specific to a protein biomarker that can be included in a sample as an internal standard to which endogenous peptide can be compared and quantified. This platform is extremely sensitive (femtomolar detection sensitivity), requires very little sample volume, and offers the highest degree of specificity with very short analysis times. Limitations of the platform are related to the selection of an appropriate peptide and the expense of assay development and qualification for use. For example, peptides need to be designed that are isoform specific, being able to discriminate between two similar but not identical proteins. Peptide design is also somewhat empirical with respect to finding peptides that will "fly" in the instrument and produce a robust signal at the detector. The choice of peptides available in a particular target may be limiting given these design restrictions. Consequently, not all proteins may be amenable to this approach.

In conclusion, continued improvement in technology platforms combined with the availability of reagents to detect new biomarkers of nephrotoxicity provides both the clinician and the investigator with a variety of tools to predict and monitor early or acute kidney injury. This will be of tremendous value toward saving lives in the clinic and developing safer, more efficacious drugs without nephrotoxic side effects.

# TRANSLATIONAL MEDICINE—A PARADIGM SHIFT IN MODERN DRUG DISCOVERY AND DEVELOPMENT: THE ROLE OF BIOMARKERS

Giora Z. Feuerstein, M.D., Salvatore Alesci, M.D., Ph.D., Frank L. Walsh, Ph.D., J. Lynn Rutkowski, Ph.D., and Robert R. Ruffolo, Jr., Ph.D.

*Wyeth Research, Collegeville, Pennsylvania*

## DRUG TARGETS: HISTORICAL PERSPECTIVES

Drugs are natural or designed substances used deliberately to produce pharmacological effects in humans or animals. Drugs have been part of human civilizations for millennia. However, until the very recent modern era, drugs have been introduced to humans by empiricism and largely by serendipitous events such as encounters with natural products in search of food or by avoiding hazardous plants and animal products. The emergence of the scientific era in drug discovery evolved alongside the emergence of physical and chemical sciences at large, first as knowledge to distill, isolate, and enrich the desired substance from its natural environment, followed by deliberate attempts to modify natural substances to better serve the human needs and desires.

Scientific evolution throughout the past two centuries enabled identification of biologically active substances in humans (e.g., hormones) which were

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

manipulated chemically to improve (potency, duration of action, and exposure), or to mitigate or abrogate undesirable actions. The cumulative knowledge of human, animal, and plant biology and chemistry provided the scientific foundation and technical capabilities to alter natural substances purposely in order to improve them. Such evolution marked the era of *forward pharmacology*. The era of forward pharmacology is about drug design that emanates from primary knowledge of the action of the biological target that has clear biological action.

The exponential progress in molecular biology since the mid-twentieth century, culminating in deciphering the complete human genome in the year 2000, brought the dawn of *pharmacogenomics* and the *reverse pharmacology* era. The reverse pharmacology era is defined by the need, first, to clarify the biology and medical perspectives of the target so as to qualify it as a drugable and pharmaceutically exploitable for drug discovery and development scheme. The pharmacogenomic era provides vast opportunities for selection of new molecular targets from a gamut of approximately 30,000 primary genes, over 100,000 proteins, and multiples of their translational and metabolomics products. Thus, the permutations in respect to opportunities for pharmacological interventions are unprecedented, vast, and most promising for innovative medicines.

The pharmacogenomics era as a source for drug targets also poses unprecedented hurdles in selection, validation, and translation into effective and safe drugs. New technologies continue to drive efficiency and robustness of mining the genomic drug discovery opportunities, but physiological and integrated biology knowledge is lagging. In this perspective, translational medicine and biomarkers research have taken center stage in validation of the molecular target for pharmaceutical exploitation.

In this chapter we offer a utilitarian approach to biomarkers and target selection and validation that is driven by the translational medicine prospect of the target to become a successful drug target. We hereby offer classification and analytical process aimed to assess risk, innovation, feasibility, and predictability of success of translating novel targets into successful drugs. We provide clear definitions of the type of biomarkers that are the core of translational medicine and biomarkers research in modern pharmaceutical companies.

## BIOMARKERS: UTILITARIAN CLASSIFICATION

Biomarkers are the stepping-stones for modern drug discovery and development [1–4]. *Biomarkers* are defined as biological substances or biophysical parameters that can be monitored objectively and reproducibly and used to predict drug effect or outcome. This broad definition is, however, of little utility to the pharmaceutical process since it carries no qualification for the significance and use of the biomarker. The following classes and definitions of biomarkers are therefore offered:

1. *Target validation:* biomarkers that assess the relevance and the potential for a given target to become the subject of manipulation that will modify the disease to provide clear therapeutic benefits while securing a sufficient therapeutic index of safety and tolerability.
2. *Compound-target interaction biomarkers:* biomarkers that define the discrete parameters of the compound (or biological) interaction with the molecular target. Such parameters include binding of the compound to the target, its residency time on the target, the specific site of interaction with the target, and the physical or chemical consequences to the target induced by the compound (or biological).
3. *Pharmacodynamic biomarkers:* biomarkers that predict the consequence(s) of compound (biological) interaction with the target. The pharmacodynamic biomarkers include events that are desired therapeutically and adverse events based on mechanism of action. Pharmacodynamic biomarkers can report on discrete molecular events that are proximal to the biochemical pathway that is modified by the manipulated target or remote consequences such as in vivo or clinical outcomes (morbidity or mortality). Pharmacodynamic biomarkers are diverse and frequently nonobvious. Advanced and sophisticated bioinformatics tools are required for tracking the divergence and convergence of signaling pathways triggered by compound interaction with the target. A subset of the pharmacodynamic biomarkers are consequences induced by the compound outside its intended mechanism of action. Such pharmacodynamic effects are often termed "off-target" effects, as they are not the direct consequence of the compound interaction with the target. Usually, such pharmacodynamic events are due to unforeseen lack of selectivity or metabolic transformations that yielded metabolites not present (or detected) in the animals used for safety and metabolic studies prior to launch of the compound into human trials or into human use. These issues are not dealt with in this chapter.
4. *Disease biomarkers:* biomarkers that correlate statistically with the disease phenotype (syndrome) for which therapeutics are developed. Correlation of levels (in the circulation, other fluids or tissue) or expression patterns (gene, protein) in peripheral blood cells or tissues should signify disease initiation, progression, regression, remission, or relapse. In addition, duration of aberrantly expressed biomarkers could also be associated with risk for disease, even if the level of the biomarker does not change over time. Since disease biomarkers are defined by their statistical correlation to features of the disease, it is imperative that the clinical phenotyping is clearly defined. Stratification of all possible phenotypic variables is clearly a prerequisite for accurate assessment of the discrete relationships of the biomarker to the disease. Gender, age, lifestyle, medications, and physiological and biochemical similarities are

often not sufficiently inclusive, resulting in a plethora of disease biomarker claims that are often confusing and futile.

5. *Patient selection:* biomarkers that are used for selection of patients for clinical studies, specifically proof-of-concept studies or confirmation phase III clinical trials that are required for drug registration. These biomarkers are important in helping to select patients likely to respond (or conversely, not respond) to a particular treatment or a drug's specific mechanism of action, and potentially predict those patients who may experience adverse effects. Such biomarkers are frequently genetic (single-nucleotide polymorphism, haplotypes) or pharmacogenomic biomarkers (gene expression), but could be any of the primary pharmacodynamic biomarkers. Biomarkers for patient selection are now mainstream in exploratory clinical trials in oncology, where genotyping of tumors in view of establishing the key oncogenic "driver(s)" are critical for the prediction of potential therapeutic benefits of modern treatments with molecular targeting drugs. The success of the new era of molecular oncology (as compared to the cytotoxic era) will depend largely on the ability to define these oncogenic signaling pathways via biomarkers such as phosphorylated oncogenes, or the functional state due to mutations that cause gain or loss of function.

6. *Adaptive trial design:* The objectives of adaptive design trials are to establish an integrated process to plan, design, and implement clinical programs that leverage innovative designs and enable real-time learning. The method is based on simulation-guided clinical drug development. In a first step, the situation is being assessed, the path forward and decision criteria defined, and assumptions analyzed. Adaptive trials have become an enabler strategy, and they work to integrate competing positions and utilities into a single aligned approach and to force much clearer articulation and quantification on the path forward. Once this framework is established, a formal scenario analysis that compares the fingerprints of alternative designs through simulation is conducted. Designs that appear particularly attractive to the program are further subjected to more extensive simulation. Decision criteria steer away from doses that are either unsafe or nonefficacious and aim quickly to hone in onto the most attractive dose range. Response-adaptive dose-ranging studies deploy dynamic termination rules (i.e., as soon as a no-effective-dose scenario is established, the study is recommended for termination). Bayesian approaches are ideally suited to enable ongoing learning and dynamic decision making [5]. The integrator role of adaptive trials is particularly strong in establishing links between regulatory accepted "confirm"-type endpoints and translational medicine's efforts to develop biomarkers. Search for biomarkers that may enable early decision making need to be read out early to gain greater confidence in basing decisions on them. A biomarker can be of value even if it only

allows a pruning decision. These considerations highlight the importance of borrowing strength from indirect observations and use mathematical modeling techniques to enhance learning about the research question. For example, in a dose-ranging study, it is assumed that there should be some relationship between the response of adjacent doses, and this assumption can be used to model an algorithm. Both safety and efficacy considerations can be built into this model: ideally, integration of all efforts, from disease modeling in discovery to PK/PD modeling in early clinical development to safety/risk and business case modeling in late development [4–7].

The utility of this system is represented in Figures 1 and 2, which suggest a semiquantitative scoring system that helps assess the strength of the program

**Figure 1** Criteria for biomarker scoring.

**Figure 2** Type I biomarkers: target validation translational medicine perspectives. CMI, chronic myelocytic leukemia; DVT, deep vein thrombosis; FV, factor V; MG, myasthenia gravis; AchR, acetylcholine receptor; GPIIb/IIIa, platelet integrin receptor; GFRK, growth factor receptor kinase; MOA, mechanism of action; AE, adverse effects.

overall and identification of the areas of weaknesses in each of the biomarkers needed along the compound (biological) progression path. Figure 3 illustrates the continuum of biomarkers research, validation, and implementation along the complete time line of drug discovery and development, including life-cycle management (phase IV) and new indication (phase V) when appropriate. Figure 3 illustrates the interfaces of translational medicine within the traditional drug discovery and development process, while Figure 4 represents the new model of "learn and confirm," where biomarkers figure prominently in driving the "learn" paradigm.

A program for which a STRONG score is established across all five biomarkers' specifications provides confidence of the likelihood for success from the biological and medical perspectives and is likely to result in a more promising development outcome. Similarly, it would be prudent to voice concerns regarding programs that score WEAK, especially if low scores are assigned to target validation, pharmacodynamic, and in special cases, target-compound interaction (e.g., central nervous system target). This scoring system is complementary to other definitions of biomarkers based on certain needs. For example, surrogate biomarkers as defined by the U.S. Food and Drug Administration (FDA) are markers that can be used for drug registration in

**Figure 3** Building translational medicine via biomarker research. (*See insert for color reproduction of the figure.*)

**Figure 4** Translational medicine: biomarker implementation along the pipeline. Exp, exploratory phase; Pre-Dev, predevelopment track; CR&D, clinical research and development; LCM, life-cycle management.

lieu of more definitive clinical outcome data. Surrogate biomarkers are few and difficult to establish (e.g., blood pressure and cholesterol; Figure 2).

## PRINCIPLES OF TARGET SELECTION

Two key guiding principles are essential in the early selection process of molecular targets:

1. Modulating the target carries the prospect of unequivocal medical benefit (efficacy) to patients beyond a standard of care.
2. Benefits can be garnered while maintaining a sufficient level of safety that can be realized within the attainable compound exposure.

Such a mission is frequently unachievable, and hence establishing an acceptable *therapeutic index* is the practical goal for most drug development schemes. Commonly, a therapeutic index is established by calculation of the ratio of the maximum tolerated dose (MTD) and the minimum effective dose (MED) in animal efficacy and safety studies. In this light, targets selected for drug development can be classified with respect to risk assessment based on the following categories (Figure 2):

*Class A.* The target is only present and contributing to the disease process.

*Class B.* The target is present physiologically but in a nonactive form, but then is activated and contributes to the disease.

*Class C.* The target functions physiologically but in an augmented, uncontrolled fashion that contributes to the disease.

*Class D.* The target functions in normal states and indiscriminately in disease (e.g., no difference in target expression, functions, or distribution can be identified in disease as compared to the normal physiological state).

### Class A: Disease-Specific Target

A disease-specific molecular target should be a molecule that operates only in the disease state and does not participate in physiological (normal) functions. Drug interaction with such targets should provide efficacy with the lowest chance for mechanism-based adverse effects when manipulated by drugs. Examples of such targets are genetic disorders, which result in either overactivity or loss of activity of the target. Such is the case in chronic myelogenous leukemia (CML), which results from aberrant recombination of DNA from chromosome 22 into chromosome 9 (Philadelphia chromosome), fusing the *Bcr* and *Abl* genes into an overacting tyrosine kinase, which drives oncogenic transformation. To cure the disease, potent and selective inhibitors of

this aberrant kinase had to be discovered, a task that took over a decade to accomplish [8]. Such targets have the potential for a high safety profile. It is however, important to note that this example may not necessarily represent the ultimate approach for this disease since the activity of the kinase (*Bcr*/*Abl*) is driven by the *Abl* kinase catalytic site, which is preserved in its physiological format. Thus, inhibitors of this target/kinase by drugs such as Gleevec may still carry the potential for interference in tissue and cells in which the *Abl* kinase is physiologically active.

Another example that is applicable to this category is a disease such as myasthenia gravis, where specific antibodies that block the acetylcholine receptors cause progressive muscle weakness. Specific neutralizing agents to these antibodies are likely to provide high efficacy in treating the disease, with the likelihood of fewer adverse effects [9] since such antibodies are not physiologically present in human beings. These examples are typical for type 1 class A target validation. The biomarkers that need to be established for this category should focus on validating the specificity of the target to the disease state.

### Class B: Target Present Physiologically in a Nonactive Form but Is Activated and Contributes to the Disease

This class of targets has little or no discernible physiological activity in normal states, yet in certain pathophysiological situations, the target is presented, activated, and plays a role in a pathophysiological event. Example of such targets in the type 1 class B category is the P-selectin adhesion molecule. This adhesion molecule is normally cryptic within platelets and endothelial cells. Upon activation of these cells, P-selectin is presented on the surface of the cell and mediates adhesion interaction with its ligand, a mechanism believed to play a role in thrombosis and inflammation. Inhibitors of P-selectin binding to its ligand, the P-selectin glycoprotein ligand (PSGL-1), are expected to provide clinical benefit with a lower likelihood of adverse events. To validate this situation, biomarkers that confirm the preferential role of the activated target in a pathophysiological process while maintaining little physiological function are essential.

However, one must be aware of potentially serious limitations to this approach where cryptic targets in the physiological state that are activated in pathological conditions and where inhibition of the target may not only provide for significant therapeutic benefit, but where inhibition of such a target may also expose the patient to some other risk, such as loss of host defense from injury. Such is the case of the platelet adhesion integrin molecule, GPIIb/IIIa, which serves as the final common pathway for platelet aggregation. Interfering with activated GPIIb/IIIa binding to its ligand (e.g., fibrinogen) provides effective and often lifesaving therapy in patients with acute risk for thrombosis; however, chronic treatment with GPIIB/IIIa antagonists have not been particularly effective in providing benefits, due to the

relatively high frequency of significant adverse effects due to bleeding since platelet adhesion to matrix protein is essential to seal bleeding sites in trauma and disease conditions. Thus biomarkers for this class must establish the full physiological significance of the target in order to assess the therapeutic index of tolerability (benefits as well as risks).

### Class C: Target Functions Physiologically but in an Augmented, Uncontrolled Fashion That Contributes to the Disease

This class of targets includes molecules that play an active role in normal physiological processes, some of which may be critical to health. Such is the neurotransmitter glutamate in the central nervous system, which is essential to cognition, memory, thought processes, and state of arousal. However, in ischemic stroke or asphyxia, glutamate release is uncontrolled and reaches to high levels over prolonged periods that are believed to be neurotoxic and likely contribute to neuronal death following a stroke. Inhibitors of glutamate release or antagonists of its action at various receptors are believed to carry the potential for effective treatment for stroke provided that the inhibition of excess release of the neurotransmitter can be achieved in a timely manner and only to an extent that preserves the physiological need of this transmitter, and over short periods (only that limited period where excess glutamate is neurotoxic). Such targets may be pharmaceutically exploitable when their manipulation is tuned carefully to the pathophysiological context.

Another example of a target in this category includes the human growth factor receptor kinase (hGFRK) inhibitor, Herceptin, which in certain cancers (e.g., breast cancer) is constitutively activated and participates in the oncogenic drive. Inhibition of the hGFRK, while clearly of therapeutic value in breast cancer, has also been associated with heart failure due to the physiological role of GFRK in the cardiac myocyte survival signaling pathway [10]. Thus, the biomarker challenge in modulation of class C targets of this nature is in identifying biomarkers that assess the needed "titration" for inhibition of the target activity only to an extent that is necessary for the maintenance of normal physiological function.

### Class D: Target Maintains Physiological Functions in Normal and Disease States

This class of targets encompasses the largest group of molecular targets exploited so far by modern drugs. Many members of this class have yielded highly beneficial therapies. This class consists of molecular targets that are known to have important physiological functions, which cannot be differentiated within a disease context; that is, the target is not different in its expression levels (gene, protein) or signaling pathway in normal and disease states. A priori, such targets harbor the greatest risk for mechanism-based adverse effects, as there is no apparent reason to expect that modulation of the target in the disease state will spare the normal physiological function of the target.

Examples of such targets include the coagulation factor inhibitors (e.g., FIX, FXa, and thrombin), which are critical to maintain a physiological level of homeostasis; hence, inhibition of these targets carries inherent bleeding liabilities. Similarly, all current antiarrhythmic drugs (e.g., amiodarone, lidocaine, dofetilide), while effective in treating life-threatening arrhythmias, all carry significant liability for mechanism-based pro-arrhythmic effects and the potential for sudden death. The biomarker challenges for this class are defining the fine balance needed between efficacy in the disease context and expected safety limitations. Biomarkers that define the acceptable therapeutic index are key to the successful utility of drugs that modulate such targets. However, targets in this class do not necessarily exhibit a narrow safety margin for clinically meaningful adverse effects. Significant examples are the L-type $Ca^{2+}$ channel blockers. The L-type $Ca^{2+}$ channel is an essential conduit of $Ca^{2+}$ needed for "beat by beat" $Ca^{2+}$ fluxes that secure precise rhythm and contractility of the heart, skeletal muscle, neuronal excitability, and hormone and neurotransmitter release. Yet L-type $Ca^{2+}$ channel blockers are important and sufficiently safe drugs that are used to treat hypertension, angina, and cardiac arrhythmias with undisputable medical benefits. However, inherent to the L-type $Ca^{2+}$ channel blockers in this class of targets are mechanism-based adverse effects associated with rhythm disturbances, hypotension, edema, and other liabilities.

Probably the best example for system specificity of physiological targets that provide major medical benefits with a high safety margin is the renin–angiotensin–aldosterone (RAAS) system. The RAAS is an important blood pressure, blood volume, and blood flow regulatory system, yet its manipulation by several different pharmacological agents (rennin inhibitors, angiotensin I converting enzyme inhibitors, angiotensin II receptors antagonists) has yielded highly beneficial drugs that reduce risk of morbidity and mortality from hypertension, heart failure, and renal failure, despite the fact that the system does not demonstrate significant operational selectivity between normal and disease states (especially hypertension). However, mechanism-based hypotension and electrolyte disturbances can limit the therapeutic benefit of these drugs, and elicit significant adverse effects when the RAAS is excessively inhibited [11]. The biomarker challenge for these targets is to define the relative or preferential role of the target in its various physiological activities, where minor manipulation in one organ might provide sufficient therapeutic potential while providing a low likelihood for adverse effects that result from more substantial inhibition of the same target in other organs.

## SUMMARY

The analysis and classification offered in this chapter regarding biomarkers in drug discovery and development aim to highlight the need for careful study and analysis of the significance of the target selected for therapeutic intervention as the first crossroad for success or failure in the development of effective

and safe drugs [12]. The analysis and utility of biomarkers along the process of drug discovery and development have become an integral part of the "learn and confirm" paradigm of drug discovery and development in leading pharmaceutical organizations such as Wyeth Research. Such analyses are useful to guide the "learn phase" in search for biomarkers that can better assess the benefits and risks associated with manipulation of the molecular target.

The scope of this chapter does not allow for a detailed review of the "learn and confirm" paradigm, for which the readers are directed elsewhere [13,14]. Various technological and strategic activities are needed to establish the biomarker strategies for the various targets described. The need to address these issues via biomarker research, validation, and implementation beginning at the very early stages of the drug discovery and development process is emphasized. In the pharmaceutical setting, it means beginning efforts to identify biomarkers for all five categories listed above. Such efforts could begin even before a tractable compound (biological) is in hand, a time where target validation is a clear focus of the program. As a compound becomes available, compound–target interaction, pharmacodynamic (efficacy and safety) biomarkers, and strategies for patient selection and adaptive design needs must be explored. At the onset of the first-in-human studies, all strategies, plans, and biomarker research should be as well worked out as possible. We believe that fundamental changes in the structure, function, and interfaces of pharmaceutical R&D are urgently needed to provide a key role for translational medicine and biomarkers research toward more successful discovery and development of innovative medicines.

## INTRODUCTION

Throughout history, biological and pathogenic processes have been measured to monitor health and disease. The presence of "sweetness" in urine and blood was recognized thousands of years ago as an indication of the disorder now known as diabetes. By recent example, the characterization of infections has been achieved by performing cultures for microorganisms, both for identification and to establish sensitivities to antibiotics. Any such measures, however variously quantitated, were forerunners of what are now popularly referred

to as biomarkers. When clinical laboratories became well established after the middle of the twentieth century, many components of body fluids and tissues were assayed. These are all biomarkers of the physiological state of being. Modern biomarkers being discovered or sought are pursued and measured based on the same principles as the first, most rudimentary of disease indicators. Hundreds of biomarkers are now used in modern medicine for the prediction, diagnosis, and prognostication about disease, as well as for monitoring preventive or therapeutic interventions. A sizable challenge now lies in selecting novel biomarkers that are most appropriate for clinical use in the face of many new candidates being suggested by various investigators.

Biomarkers are often thought of as strictly molecular in nature, but in fact they include a vast range of objectively measurable features. Any characteristic that reflects a normal biological process, pathogenic process, or a pharmacologic response to an intervention can potentially become a clinically useful biomarker [1]. Thus, there are many different types of biomarkers, including molecular, physiological, or structural features of biological systems. However, how a specific measure reaches the status of customary has not been so clearly established.

The focus on using biomarkers in clinical decision making and diagnosis has expanded, and similarly, biomarkers are playing an ever-increasing role in drug development processes and for regulatory decision making. As drug development costs continue to rise, biomarkers have become increasingly important, as they are a potential means to decrease the time for development, costs, and late-phase attrition rates in the regulatory approval process for new drugs:

- Reduce clinical trial costs:
  - Decrease late-phase attrition rates.
  - Replace time-consuming clinical endpoints.
- Reduce required clinical trial sample size by way of patient stratification:
  - Identify the population most likely to benefit.
  - Identify the population with a high level of risk for events of interest.
- Provide more robust assays than some conventional clinical endpoints.
  - Help improve models for calculating return on investment.

For example, cost and time can be reduced when biomarkers help to segment patient groups early in trials, and some new markers may be more timely than many of the more traditional clinical endpoints or outcomes used currently in assessing clinical trials, such as patient survival [2,3]. Biomarkers are also beneficial tools for selecting the best candidates for a trial or to increase safety through more effective drug monitoring. Ultimately, by reducing the required time investment to demonstrate a drug's safety and efficacy,

biomarkers may greatly reduce the costs and risks of performing a clinical trial.

## BIOMARKER DISCOVERY, DEVELOPMENT, AND TRANSLATION

Biomarker discovery can be performed using animal models, but it is now commonly carried out in humans from the very beginning stages of biomarker development. Biomarkers analyzed in preclinical animal studies are eventually transferred to the human, clinical settings. In a controlled laboratory environment the conditions are relatively constant, and "subjects" (i.e., the animals) are homogeneous and free of complicating co-morbidities. In these laboratory settings there are generally more options regarding the assays available, and the possibility of frequent and repeated testing in individual animals or groups of similar or identical animals allows for changes in the measured matrix of analytes to be detected with high precision and sensitivity. Ideally, a candidate biomarker discovered in this fashion would then be transferred into the clinical environment and evaluated further on human samples. The drawback of this approach is that many of the biomarkers discovered in animal models cannot be translated for use in humans. Animal models often do not accurately reflect human biology [4]. Further, the biomarker candidate may not achieve acceptable performance standards in heterogeneous patients with age, gender, and racial differences. This is why it has been suggested that pilot studies of biomarkers be conducted in humans first, in early phase II clinical trials that incorporate the variability in various ambient influences, and then that the marker be validated in preclinical studies, and in a later stage, clinical trials in parallel. This approach expedites the biomarker development process and minimizes the attrition rate of biomarker candidates since they are developed from the beginning under human clinical conditions.

In patients, biomarker candidate discovery is performed preliminarily in an internal primary cohort and is confirmed subsequently in an external secondary cohort. These two discovery phases are typically performed in observational or retrospective cohorts, and less and less often in preclinical studies. Some companies are avoiding animal models for discovery all together to avoid spending time and money on animal-based biomarkers that can often lead to a dead end.

It is not always practical to pursue validation of biomarker candidates identified in the discovery process. It is important to establish parameters for rational, statistically sound, and evidence-based selection and rejection of candidate biomarkers [5–7]. The decision to continue development of a biomarker candidate is largely based on its potential to contribute cost-effectively to disease management [8]. Biomarkers used in the early phases of clinical development may be useful in providing more timely proof of concept or dose-range information than a real clinical endpoint [9]. Biomarker development should also be driven by clinical need [8]. A clinically useful biomarker

must favorably affect clinical outcomes such as decreasing toxicity or increasing survival [10].

Once cost-benefit ratios are evident and more than one institution has consistently confirmed a biomarker's ability to perform at the requisite levels of sensitivity and specificity, a biomarker is ready for prospective testing in clinical trials [8]. The U.S. Food and Drug Administration (FDA) pharmacogenomic submission guidelines recommend that transferring genomic biomarker sets from microarrays to other platforms (such as quantitative real-time polymerase chain reaction) be attempted only once it has been demonstrated that the differential expression of such genes is sensitive, specific, and reproducible. Analytical quality assurance is performed continually throughout biomarker and drug development for most biomarkers; however, if a biomarker is to be used as an endpoint in a phase III efficacy study, it should be validated beforehand [11]. Assay and analytical specificity and sensitivity should be established and validated prior to clinical phases such that clinical qualification can be carried out using proven, analytically robust methods [12]. However, as biomarker and drug development are intertwined processes, they may often occur concurrently throughout the different stages of clinical trials.

## BIOMARKER VALIDITY AND VALIDATION: THE REGULATORY PERSPECTIVE

The FDA's *Guidance for Industry: Pharmacogenomic Data Submission*, published in 2005, has helped introduce and define exploratory and valid biomarkers. The FDA defines a *valid pharmacogenomic biomarker* as one that is measured in an analytical test system with well-established performance characteristics and for which there is an established scientific framework or body of evidence that elucidates the toxicological, pharmacological, or clinical significance of the test result. The FDA further classifies valid biomarkers as "probable" and "known" in terms of the level of confidence that they attain through the validation process. *Probable valid* biomarkers may not yet be widely accepted or validated externally but appear to have predictive value for clinical outcomes, whereas *known valid* status is achieved by those that have been accepted in the breadth of the scientific community.

It is important to realize that the different classes of biomarkers reflect their levels of confidence (Figure 1). This can be thought of in a hierarchical manner, with exploratory biomarkers being potential precursors of clinically useful (probable or known) valid biomarkers [13].

Integrating biomarkers into clinical trials for eventual clinical use by identifying the best or most valid biomarker candidates is not a clearcut process. The term *validity*, particularly in the field of biomarkers research, is a broad concept that has been used to describe everything from the analytical methods to the characteristics of the biomarkers identified [14]. Validity is also used across multiple industries, not only medical or health disciplines. Therefore,

**Figure 1** Biomarker validation. Biomarker development and validation are driven by intended use or fit-for-purpose (FFP). The principle of FFP validation is that biomarkers with false-positive or false-negative indications pertaining to high patient consequences and risks necessitate many phases of validation. There are five phases of validation that can be executed with the stratified use of various bioinformatical and bibliographical tools as well as different designs, statistical approaches, and modeling: (1) internal validation, (2) external validation, (3) clinical trials (phases I and II; checking for safety and efficacy), (4) large clinical trials (phase III), and (5) continued surveillance. Sensitivity and specificity correlate with the intended purpose of the biomarker, and the level of confidence that a biomarker achieves depends on the phase of validation that has been reached. In ideal cases biomarkers reach surrogate endpoint status and can be used to substitute for a clinical endpoint. This designation requires agreement with regulatory authorities, as the consequences of an ambiguous surrogate endpoint are high.

when referring to biomarkers, validation is sometimes termed *qualification* for clarity. Biomarker qualification has been defined as a graded *fit-for-purpose* evidentiary process linking a biomarker with biology and clinical endpoints [15,16].

Traditionally, the validity of clinical biomarkers has become established in a typically lengthy process through consensus and test of time [17]. Now more than ever, clear guidelines for validation are needed, as technological advances have drastically increased biomarker discovery rates. With the recent explosion of "omics" technologies and advancements in the fields of genomics, proteomics, and metabolomics, high-throughput biomarker discovery strategies are now widely used. This has created some unforeseen issues. Biomarker

**Figure 2** FDA biomarker qualification pilot process. (Adapted from ref. 17.)

candidate discovery now commonly outruns the rate at which the candidates are being validated, creating a bottleneck in biomarker (assay) development [18,19]. Great efforts are now being undertaken to accelerate the acceptance of biomarkers from exploratory to valid, as the goal of many research teams and drug companies is to streamline the translation of biomarker from basic science and discovery to clinical use [12].

Despite the definitions provided by the FDA and the availability of FDA's *Guidance for Industry: Bioanalytical Method Validation* in 2001, there is still a lack of sufficient regulatory guidance for biomarker validation. The FDA has designed a qualification process map that sets the foundational framework toward establishing validation guidelines (Figure 2). This pilot structure, to start qualification processes for biomarkers in drug development, is designed around various FDA centers whereby the context and qualification of new biomarkers is assessed. Ultimately they are rejected or accepted for suggested use relative to current biomarkers. This may not be ideal, as it may be problematic to establish new biomarkers accurately based on the current biomarkers, which are themselves often imperfect relative to a specific endpoint [17]. Nonetheless, this pilot framework will eventually enable more detailed biomarker translation models, which address some of the remaining issues with the current guidelines, to be developed.

There remains a lack of specific guidelines on which validation process(es) are recommended or expected in order to transition effectively from exploratory to valid biomarkers, or from probable valid biomarkers into known valid biomarkers [13,20]. Confusion still exists with regard to analyses or experiments that need to be performed and data that are both appropriate and sufficient for biomarker (assay) validation [20].

The confusion and inconsistency in the validation process are contributed to partially by the diverse nature of biomarker research [3,20]. Considering the large variety of novel biomarkers, their applications, and associated analytical methods, it is unlikely that FDA regulations or other available guidelines will easily be able to address validation issues associated with all possible research objectives [16,20]. Thus, it is incredibly difficult to establish, let alone use, a specific detailed universal validation guideline [20].

## FIT-FOR-PURPOSE STRATEGY

Despite the lack of universal guidelines or agreement on the specific requirements for biomarker assay development and validation, there is a general consensus in the biomarker research community that the foundation of validation efforts is to ensure that the biomarker(s), or the assay, is "reliable for its intended use" [20]. This principle is now commonly referred to as the *fit-for-purpose validation strategy* or guideline. This approach embraces the notion that depending on the intended purpose of the biomarker, the objectives and processes or types of validation will probably be different [21,22]. Dose selection, early efficacy assessment or candidate selection, and surrogacy development are all examples of biomarker clinical purposes, each of which have differing levels of validation requirement. The risk and consequence may be different depending on the purpose, even when the same biomarker is used [4].

Further, the degree of stringency and phase of the validation, both of which are discussed later in the chapter, should be commensurate with the intended application of the validation data (Figure 1) [22]. In that sense, the term *validity* should be thought of as a continuum—an evaluation of the degree of validity—rather than an all-or-none state [14,23]. Therefore, biomarker utility is not measured dichotomously and should not be classified as simply good or bad. The level of a biomarker's worth is gauged on a continuous scale, with some being much more valuable than others, depending on what they indicate and how they can be applied [24]. Validation of biomarkers and establishment of their "worth" or "value" is a continually evolving and often iterative process (Figure 1).

### Application of the Fit-for-Purpose Strategy

The fit-for-purpose (FFP) strategy is a fluid concept that can be applied to any clinical trial to validate biomarkers of interest. As described earlier, the classification and validation of a biomarker is context-specific, and the validation

criteria required are dependent on the intended use of the biomarker. The concept of fit-for-purpose validation is sensible, as biomarkers may be used to include or exclude patients from treatment and to determine dosing, toxicity, or safety. The consequence or risk of a false-negative or false-positive biomarker indication must be considered since even the most sensitive and specific assays are not perfect. A biomarker intended as a population screen must be very sensitive and extremely specific [25]. Any tests that are to be used in isolation for decision making require particularly stringent validation, whereas drug efficacy biomarkers that are typically used in groups or involve subsequent testing may require less stringency since the consequence of a false indication of efficacy is lower [26].

### Biomarker Validation Process

Utilizing the FFP strategy, various questions can be asked at the beginning of any biomarker research and development (R&D) project: For what reason are the biomarker(s) being identified? Is the clinical validation going to validate the biomarker for specificity, sensitivity, and reproducibility for diagnostic purposes, or to serve as a surrogate endpoint? What business-critical decisions will be made based on the biomarker data? These questions not only help determine the level of confidence required for the biomarker, but also help strategize regarding the phases of validation. For example, in the case of developing surrogate biomarkers to replace clinical endpoints, candidate biomarkers would, theoretically, evolve over time toward the point of surrogacy as the research project moves through different phases of validation. For the purpose of this chapter, the validation process from initial biomarker development to postmarket surveillance has been broken down into five major phased strategies (Figure 1). It is important to note that the overall process is a continuous loop driven by the intended purpose of the biomarker data, but the flow of the overall process may be subjected to change depending on the results generated at each phase [22].

In general, the process of biomarker validation can be described as a multifaceted process that includes determining sensitivity, specificity, and reproducibility of the assay and also clinical sensitivity and specificity [27]. This applies to both methodologic and clinical validation. Method validation pertains to the process by which the assay and its performance characteristics are assessed. This assessment is performed throughout biomarker translation and is based on several fundamental parameters: accuracy, precision, selectivity, sensitivity, reproducibility, and stability [16,22]. Method validation is not discussed in detail in this chapter.

## PRECLINICAL AND CLINICAL VALIDATION PHASES

Clinical validation is the documented process demonstrating the evidentiary link of a biomarker with a biological process and clinical endpoints [15,16].

**Figure 3** Biomarker development and translation. Biomarker translation from discovery to clinical use involves five general steps or phases. Biomarker candidates are initially discovered in a primary (internal) cohort and confirmed in a secondary (external) cohort through clinical observations. Biomarker candidates that have the best fit-for-purpose and also satisfy a clinical need then enter prospective phase I and II clinical trials. Once a biomarker is used in these early clinical trials to demonstrate safety and efficacy, they may be considered "initially validated biomarkers." Following large-scale clinical trials (phase III), and once biomarkers have been used for decision making, they may be considered valid and may be adopted for clinical use. Biomarker assessment continues in postmarket phase IV trials. SOP-driven analytical quality assurance is performed throughout all processes of biomarker translation.

The validation process whereby biomarkers are translated from discovery to clinical use should be customized according to biomarker type, use, variability, and prevalence. However, the general process for validating any biomarker is the same. Before any biomarker can be applied clinically, it is subjected to analytical/method validation and also clinical validation. Biomarker validation can be performed in five general translational steps: preliminary biomarker discovery, biomarker discovery, safety and efficacy clinical trials, large-scale clinical trials, and continued surveillance (Figure 3).

Clinical biomarkers are validated in retrospective or prospective analyses and biomarker trials, or drug trials [12]. The validation process should reflect the clinical performance of the biomarker(s), based on existing clinical data, new clinical data, literature review findings, or current clinical knowledge [12]. Moreover, it should be an evidentiary and statistical process that aims to link

a biomarker to specific biological, pathological, pharmacological (i.e., drug effect), or clinical endpoints [22].

## Internal Validation

During the biomarker discovery phase, the main focus is to identify biomarkers that distinguish between the treatment and control groups or correlate with the clinical observation of interest. Prior to this process, and depending on the sample size, plans can be made to allocate the subjects into two individual cohorts for the purpose of internal validation. It is important, however, to distinguish this allocation/splitting process from that used for the purpose of internal validation of classifiers:

- Internal validation of candidate biomarkers identified in the discovery cohort
  - Use of different platforms
  - Use of different statistical methods
- Internal validation of classifiers
  - Split-sample method
  - Some form of cross-validation method

There are several different approaches to separate the initial pool of patients or samples for internal validation and creating classifiers; the traditional and alternative approaches are outlined here. Traditionally, a *discovery* and a *validation* cohort are created (Figure 4). Genomic biomarker candidates may first be identified in the discovery cohort using microarray analysis, for example. One way of identifying a panel of biomarkers from the candidates is by use of classification methods. The samples from the discovery data set can be split into a *training* set, used to find a classifier, and a *test* set, used for internal validation of classifiers. The classifier is an equation combining the expression values of some of the candidate markers that best distinguish the treatment from the control group. Once the classifier has been developed, the panel of biomarkers may be validated again in the validation cohort before the external validation phase is carried out. In this sense, the data obtained in the validation cohort serves purely as an additional test set.

Although the traditional internal validation model is simple and logical, it may not be the most applicable strategy in the real world, given the complexity of most biomarker research today. There are two potential weaknesses to this approach. First, separating available samples into discovery and validation cohorts from the outset might unintentionally restrict the use of the samples or data to their arbitrary labels. In reality, during the developmental phase of biomarker research, different statistical analyses are often carried out to identify potentially useful biomarkers. Depending on the types of comparisons being made, a sample (or portion of data) could be used for discovery pur-

**Figure 4** Traditional internal validation approach. Traditional approaches to internal validation rely on two cohorts: discovery and validation. The discovery cohort is typically separated into training and test sets for the development of classifiers based on biomarker(s) of interest. The classifiers are then tested in a separate cohort internally before external validation.

poses in one analysis while it is used for validation in another. Second, in the case where the classifier fails to show acceptable accuracy in the initial discovery cohort testing set, one might consider incorporating additional data and reanalyzing the training set. However, collecting additional patient samples or information may not always be possible; this type of situation may warrant the reallocation of data from the validation to the discovery cohort training set, in order to redevelop the classifier.

An alternative model of internal validation may be particularly useful for smaller sample sizes (Figure 5). Similar to the traditional approach, the subjects are divided into two separate groups. However, neither cohort is marked strictly as discovery or validation, to minimize potential confusion in later analyses and maximize the utility of available data. As an example, a classifier can be generated and internally validated by creating training and testing sets from cohort 1. The same classifier can then be validated again in a separate cohort (cohort 2). Based on the outcome, the R&D team may decide that the classifier is ready for external validation or that a more robust classifier needs to be developed. In the latter case, a new classifier can be created by utilizing cohort 2 as the discovery cohort. Once the new classifier has been validated internally in cohort 2, it can be evaluated again in cohort 1, which is used

**Figure 5** Alternative internal validation approach, which may be particularly useful for smaller sample sizes. Like the traditional approach, the subjects are divided into two separate cohorts. However, in this model, a classifier can be developed from either cohort, or whenever necessary, from two cohorts combined to improve the robustness of the classifier.

entirely as another testing set. Finally, the same decision process is repeated: Is the classifier robust enough to stand up to the scrutiny of external validation? Are additional data required to create a new classifier? In the latter situation, it may be necessary to combine cohorts 1 and 2 to develop larger training and test sets for internal validation. This may, in turn, help create a new classifier that is potentially more robust and applicable to a larger intended patient population. The main advantage of this model is that it provides many possible internal validation approaches, particularly in a project where sample size is small. This gives flexibility to the overall validation process and allows decisions to be made based on the results generated at each step.

During the development and testing of a biomarker panel, concurrent literature and technical validations may also take place. Depending on the characteristics of the biomarker, various technology and analytical techniques may be applied. For example, quantitative polymerase chain reaction (qPCR) may be used to validate the microarray data generated from cohort 1. Once the initial findings have been confirmed, such as the differential expression of particular genomic biomarkers, qPCR can also be used to test the candidate biomarkers in cohort 2.

There are a number of potential advantages to cross-platform or cross-technology validations. Relative to high-throughput technologies such as microarray chips, which are typically used for identifying genomic biomarker candidates, the use of low-throughput techniques such as qPCR may help reduce the cost of the validation process. Also, by applying different platforms and analytical methods, biomarkers that are found to be statistically significant across the various cohorts are less likely to be related to or influenced by platform-specific bias. More recently, studies have also suggested that the use of combined data from multiple platforms (i.e., genomics and proteomics) to assess potential biomarkers is far superior to those generated with one technical approach alone [21].

The internal validation strategy will be largely dependent on the characteristics of the biomarkers (i.e., genomic, proteomic, metabolomic), the intended use (i.e., prognostic or diagnostic), and the sample size (i.e., traditional or alternative model). Nonetheless, the general recommendation is that the preliminary or developmental studies should be large enough so that either split-sample validation or some form of cross-validation can be performed to demonstrate the robustness of the internally validated prediction [28,29].

## External Validation

The use of internal discovery and validation cohorts has helped studies to develop biomarker panels with impressive accuracy and precision for the predicted outcome [28]. However, internal validation should not be confused with external validation, which is typically performed on a cohort from a different geographical location and is meant to simulate a broader clinical application [28]. Internal validation, even with the use of "independent" cohorts, does not guarantee "generalizability."

In principle, the aim of external validation is to verify the accuracy and reproducibility of a classifier in a truly independent cohort with similar underlying condition, given a defined clinical context [30]. External validation is a crucial and essential step before a classifier is implemented in a larger clinical setting for patient management [30]. Like internal validation, the design of external validation processes will depend on the intended use of the biomarker. For predictive biomarkers, prospective trials may be necessary, as they are considered the gold standard [28,30]. Moreover, it has been argued that a biomarker is more readily tested in a prospective clinical trial once retrospective studies conducted at external institutions have consistently shown the ability for the biomarker to perform at the required levels of sensitivity and specificity [8].

To accelerate the translational process from external validation to phase I and II clinical trials, partnerships and collaborations are often established. In some circumstances, classifiers may need to be tested in intended patients at a collaborators' site or external institution in a prospective manner. In other cases, retrospective studies using patient samples may suffice. There are

several important factors to consider when conducting an external validation, regardless of the directionality of the study (i.e., prospective or retrospective). Many of these factors are also critical in designing clinical trials.

## USE OF STATISTICS AND BIOINFORMATICS

Due to the complexity and multifaceted nature of biomarker research, it is not uncommon, especially in the recent years, to see different "omics" techniques, bioinformatics, and statistical methods incorporated into biomarker research and development [21]. Thus, there has been a large increase in the number of possible approaches to analytical and clinical validations. As illustrated in Figure 1, the use of bioinformatics and statistics to validate biomarkers can accompany any preclinical or clinical stage. More specifically, they are applied to a greater degree of freedom during the initial phases of biomarker development. Ideally, by the time a biomarker enters large clinical trials or is put on the market under continued surveillance, its robustness should already have been tested with the use of a variety of statistical and bioinformatical approaches. Regardless, these computational approaches, although not very stringent, are fundamentally useful tools for ensuring the validity of results prior to using some of the more time-consuming and costly validation methods (i.e., external validation or clinical trials).

### Statistical Approaches

High-throughput "omics" technologies such as microarray-based expression profiling generate massive amounts of data. As such, new statistical methods are continually being developed to deal with this challenging issue. The availability of a plethora of statistical techniques, when used with proper precautions, has provided a relatively quick and inexpensive way to validate biomarker candidates. The trial-and-error process with different statistical methods is especially common during early stages of biomarker development. In the exploratory phase of a biomarker project, various computational and mathematical techniques, such as multivariate analysis or machine learning, are often utilized to detect differences between treatment and control groups or between patients with different clinical presentations [18].

Statistically distinctive genomic biomarkers identified during the exploratory phase by one method may subsequently be subjected to a different technique. Similarly, given the same set of samples and expression measurements, permutation can be carried out on the data set prior to repeating an analysis. Congruency between the results generated using different methods may ultimately translate to an increase in biomarker confidence. This is especially useful during the internal and external phases of validation, when greater statistical freedom is exercised for the purpose of identifying or ranking biomarkers. Ideally, by the time a panel of biomarkers is selected for use in

a clinical trial, specific algorithms and statistical approaches should be established. It has been suggested in a recent FDA presentation [12] that the expression patterns or algorithms should be developed and confirmed in at least two independent data sets (a training set and a test set, respectively) [12].

### Bioinformatical and Bibliographical Approaches

Potential biomarker candidates should be checked continuously using bioinformatical and bibliographical tools to provide biological and clinical context. This step should be performed in parallel to the stratified statistical approaches. Although bioinformatics originated from the field of genomics, it now plays an important role in connecting and integrating biological and clinical data from a variety of sources and platforms [21].

Biomarkers that fit accepted theory are more likely to be accepted readily by the research community and the public [14]. This is especially important when selecting and transitioning biomarkers from internal and external validation phases into clinical trials. Numerous bioinformatical tools, many of which are open-source, are available to accelerate this evidentiary process. Gene and protein biomarker candidates can be processed first and then grouped through gene ontology using tools such as FatiGO and AmiGO [31,32]. More sophisticated pathway-oriented programs such as Ingenuity and MetaCore are also potentially useful in assisting the R&D team to zone in on biomarkers belonging to pathways and processes relevant to the clinical endpoints of interest [33,34].

Another advantage of the bioinformatical approach is the ability to link clinical measurements across platforms and/or identify a unique set of molecular signatures. For example, during external validation on a separate cohort of patients, results might indicate that the biomarkers identified initially as statistically significant were individually unable to strongly predict the clinical endpoint. However, linking expression data across platforms (i.e., genomic and proteomic biomarkers) may help provide a more comprehensive understanding of the biology and establish a stronger correlation between the biomarker and the clinical presentation of the patient [21].

## FROM EXTERNAL VALIDATION TO CLINICAL TRIALS: THE IMPORTANCE OF COHORT, TECHNICAL, AND COMPUTATIONAL FACTORS

As biomarker candidates continue to pour out of research laboratories, it has become increasingly evident that validation is much more difficult and complex than discovery. There are a multitude of general and specific considerations and obstacles to address in order to validate biomarker candidates clinically, some of which were discussed earlier and some of which we discuss now.

Translation of a candidate biomarker from a discovery phase into the validation phase of clinical trials imposes huge organizational, monetary, and technical hurdles that need to be considered at the onset. The team needs to meet requirements in sample number and feature distribution (*cohort factors*), sample quality, accuracy and precision in handling and processing the samples (*technical factors*), and in the analysis (*computational factors*). As we will see, each of these steps is extremely important and very challenging at the same time.

## Cohort Factors

During any phases of external or clinical validation of biomarkers, bias can be introduced unintentionally. This is a major concern in the design, conduct, and interpretation of any biomarker study [35,36]. Starting with the population selection process, variations at a biologically level can lead to discernible differences in body fluid and tissue compositions and biomarker measurements [35]. As such, basic criteria such as gender, age, hormonal status, diet, race, disease history, and severity of the underlying condition are all potential sources of variability [35]. Moreover, patient cohort characteristics of the validation phase of a candidate biomarker must be representative of all patients for which the biomarker is developed. To reduce a bias requires the inclusion of hundreds of patients per treatment or disease arm. Not every patient is willing to give biosamples for a biomarker study, however, and only 30 to 50% of the patients in a clinical trial may have signed the informed consent for the biomarker analysis, presenting an important concern for statisticians. There is a risk for population bias, since a specific subset of patients may donate biosamples, hence skewing the feature distribution. Another risk factor that needs to be dealt with in some instances is the lack of motivation of clinical centers to continue a study and collect samples. Although it is sometimes possible to compensate for a smaller sample size through the use of different statistical methods, such as the use of local pooled error for microarray analysis, the analysis team needs to ensure that there is no patient selection bias by the center selection: Affluent centers and their patients may have different characteristics from those with other social backgrounds.

The lack of available samples or patient enrolment may ultimately translate to a decrease in biomarker confidence or the generalizability of the intended biomarker. In reality, collaboration will probably make biomarker validation more robust and economically feasible than working independently [37]. Since the issue of intellectual property (IP) agreement is minimal for the biomarker validation *process*, as it is not patentable, open interactions among steering committees of large trials or cohort studies should be encouraged [37,38].

## Technical Factors

***Sample Collection, Preparation, and Processing*** Even with the establishment of a relatively homogeneous cohort for external validation or

clinical trials, results from the intended biomarker assays are valid only if sample integrity is maintained and reproducible from sample collection through analysis [22]. Major components of assay and technical validation are:

- Reference materials
- Quality controls
- Quality assurance
- Accuracy
- Precision
- Sensitivity
- Specificity

Prior to the start of a validation phase, the team needs to decide on the sampling procedure, sample quality parameters, and sample processing. Reproducibility is the key to successful biomarker validation. It is important that standardized operating protocols (SOPs) for sample collection, processing, and storage be established to provide guidance for the centers and the laboratory teams. Nurses and technicians should be trained to minimize the variability in sample collection and handling.

Most biomarkers are endogenous macromolecules which can be measured in human biological fluids or tissues [39]. The collection process for these specimens seems straightforward. However, depending on the type of biomarker (genomic, metabolomic, or proteomic) and the collection methods, various factors may need to be taken into account when designing the SOPs [22]. Several examples are given in Table 1.

Processing the samples in a core facility reduces the risk of handling bias, since the same personnel would handle all samples in the most reproducible way possible. Once the samples are collected, systematic monitoring of their quality over time should also be established. Random tests can be conducted to ensure the short-term, benchtop, or long-term stability of the samples to uphold the integrity of the biolibrary [38].

**TABLE 1 Sample Considerations**

| Collection (Biological Fluids or Tissues) | Preparation and Processing | Storage |
|---|---|---|
| Type of needle | Dilution | Type of storage containers |
| Type of collection tube or fixation | Plasma or serum isolation | Temperature of storage |
| Location of collection | Temperature of processing | Duration of storage |
| Time of collection | Reagents used | |
| Status of patient | | |

Unfortunately, during external and clinical validations, it is likely that the independent collaborators utilize a completely different set of SOPs. Even though this could ultimately contribute to the robustness of the validation process, it may be useful to establish specific guidelines that would help minimize site-to-site variability. There are several ways to achieve this. Provision to the laboratories and centers of kits that contain all chemicals needed for the processing of the sample can potentially reduce the risk of batch effects. Similarly, as pointed out in Figure 5, it may be feasible to collect a separate set of samples internally (to minimize sample collection variability) but send them to a collaborator's site for external validation using independent processing and analytical SOPs.

It is of utmost importance that any deviation from the SOPs is noted. These features can then later be accommodated by statisticians for better modeling. Any available information on bias or deviation from protocols or batch processing is useful in the computational process. Excluding them may influence the decision as to whether a biomarker was or was not validated.

***Sustained Quality Assurance, Quality Control, and Validation of the Biomarker Tests or Assays*** The aforementioned cohort (i.e., patient selection) and technical factors (i.e., sample collection, processing, and storage) can all have a significant impact on any of the phased strategies to biomarker validation shown in Figure 1. However, in reality, validation of the biomarker test is just as important as the validation of the biomarker itself. To improve the chance of successful translation from external and clinical validation results to patient care, the analytical validity of the test (does the test measure the biomarker of interest correctly and reliably?) should be closely monitored along with the clinical validity of the biomarker (does the biomarker correlate with the clinical presentation?) [8,12]. Furthermore, to sustain the quality assurance and quality control between different stages of biomarker development, it may be necessary to carry out multiple analytical or technical validations when more than one platform is used.

## Computational Factors

In addition to the statistical and bioinformatical factors in the validation process described earlier, the team must also be aware that a vast number of samples impose a huge computational burden on software and hardware. This is especially true when high-throughput and high-performance technologies or high-density arrays need to be used for the validation process. Not considering this potential issue may ultimately be costly in terms of money and time. To deal with the massive amount of data generated from these technologies, new statistical techniques are continuously being developed. Statistical methods should include those that were used successfully in the discovery phase. If the performance is not as good in prior analyses, the refinement of algorithms will be necessary ("adaptive statistics").

### Other Challenges of Clinical Biomarker Validation

There are many additional barriers and concerns for clinical validation of biomarkers:

- Choice of matrix (readily accessible, effect on biomarker concentrations)
- Variability (interindividual and intraindividual)
- Preparing calibration standards
- Implementations of quality control to assure reproducibility
- Limited availability of clinical specimens
- Heterogeneity of biomarkers (isoforms, bound states)
- IP protection (lack of collaboration)
- Lack of clear regulatory guidance

As discussed, the discovery and validation processes involve multicenter studies with large patient cohorts and technical equipment, steered by a vast number of staff members. The enormous costs for these studies can in most cases be covered only by consortia, consisting potentially of academic centers and pharmaceutical companies. The establishment of such consortia often has to overcome legal hurdles and IP issues, which may be a time-consuming process. As mentioned above, establishment of a biomarker may involve the recruitment of hundreds of patients per treatment arm. Both recruitment time and success rate are unpredictable at the beginning of the study phase.

It is during the initial phase that the team needs to determine what really constitutes a good biomarker. Key questions in this decision include: What is the threshold for decision making that needs to be established to call a biomarker "useful"? How do we achieve a "robust" biomarker: a marker that is not easily influenced by such factors as location and personnel? How economical does the biomarker test need to be for it to be used? Which biomarker matrix should be selected, since this may affect future validation possibilities? Accessible matrices such as urine or blood with limited or known concentration variability are ideal.

## BIAS AND VARIABILITY: KEY POINTS REVISITED

To summarize the sections above, variability is a major obstacle in biomarker validation, regardless of the matrix, the type of biomarker, and its use. As noted above, there are two types of variability: intraindividual variability, which is usually related to lab techniques, sample timing, drug effects, and within-subject biological processes, and interindividual variability, resulting from different individual responses involving multiple genetic factors [40]. Biological variability may be difficult to assess, but it is important to control

**TABLE 2 Fundamental Concerns in Biomarker Validation**

| | Concern | Solutions |
|---|---|---|
| Overfitting | False positives and negatives<br>High sensitivity and specificity found but fail on independent validation sets | Increase sample size<br>Statistical approaches<br>Receiver operator characteristic curves |
| Bias | Misidentification of differences between samples | Control for confounding factors |
| Generalizability | Can results be applied to appropriate clinical populations? | Representative validation cohorts |

for this factor. A statistical correlation to a clinical endpoint for a candidate biomarker cannot be determined without assessing biological variability, as the overall noise of a sample is a sum of both analytical and biological variability [6]. A biomarker with wide biological variability or time fluctuations that are difficult to control may be rejected [6]. Diurnal variability may require sample pooling or collection at the same time of day [6]. Biomarkers have diverse molecular structures, including possible bound states, which also need to be considered as influences on variability. There are specific considerations for any biomarker validation study. Overfitting, bias, and generalizability are three of the most fundamental concerns pertaining to clinical biomarker validation (Table 2) [41]. With the introduction of high-throughput discovery strategies, overfitting has become a particular fear. These discovery platforms are designed to measure countless analytes, and there is therefore a high risk of false discovery. When a large number of variables are measured on a small number of observations to produce high sensitivity and specificity, the results may not be reproducible on independent validation sets. Some biomarker candidates may be derived simply due to random sample variations, particularly with inadequate sample sizes [26]. A false positive may be thought of as critical part of a disease process, when in fact it is either associated only loosely or coincided randomly with disease diagnosis or progression [3]. As mentioned earlier in the chapter, a biomarker may correlate with a disease statistically but not prove to be useful clinically [8,42]. Increasing sample size and use of receiver operator characteristic curves may help overcome this concern of overfitting.

Bias is another major concern during biomarker validation, as there is often potential for misidentifying the cause of the differences in biomarkers between samples. Confounding variables such as age, race, and gender should be controlled for either through statistical modeling or validation study design to limit the effects of bias. Since validation cohorts require suitable diversity for widespread utility, bias may be difficult to avoid entirely through study design.

Similar to bias, most issues pertaining to the generalizability of a biomarker across clinical populations can be addressed through careful consideration of cohort selection. Cohort factors were discussed briefly above. To increase generalizability, the later phases of validation should include more rigorous testing of potential interfering endogenous components by including more diverse populations with less control of these confounding variables [22]. For example, in later-stage clinical trials there should be less control of diet and sample collection and more concomitant medications and co-morbidities [22]. This will allow a biomarker to be used in more clinically diverse situations.

## KEY MESSAGES

Many of the biomarkers in current clinical use have become accepted via debate, consensus, or merely the passage of time [13]. This rather unofficial establishment of biomarkers in the past has been very inefficient. Importantly, biomarkers can no longer become accepted in this way, as they would fail to meet the current regulatory standards of modern medicine. Contemporary biomarkers must be tested in highly regulated human clinical trials [43]. To date, the clinical trial process has not been very efficient, and a typical biomarker life cycle from discovery to clinical use may take decades. For example, the evolution of prostate-specific antigen (PSA) as a biomarker for prostate disease diagnosis and monitoring took 30 years for regulatory approval by the FDA [44]. In order to expand on the biomarker repertoire used currently in clinical practice, the acceptance process for new biomarkers needs to become much more efficient and cost-effective.

The general problem of lack of regulatory guidance is very likely to be addressed formally by regulatory bodies in the near future. Problems such as the availability of samples will also probably improve as collaborations are established and the ethical issues surrounding biobanks are clarified. Even if a biomarker candidate fails during validation, much may be learned regarding the pathophysiology of the disease and the corresponding drug effects during the process [9]. However, without successful validation and integration of biomarkers into clinical use, much of the research effort, particularly in terms of biomarkers for drug development, can be futile.

# PREDICTING AND ASSESSING AN INFLAMMATORY DISEASE AND ITS COMPLICATIONS: EXAMPLE FROM RHEUMATOID ARTHRITIS

Christina Trollmo, Ph.D., and Lars Klareskog, M.D., Ph.D.
*Karolinska Institute, Stockholm, Sweden*

## INTRODUCTION

Chronic inflammatory diseases include a number of rheumatic, neurological, dermatological, and gastrointestinal diseases, which develop as a result of immune and inflammatory reactions. These perpetuating reactions ultimately cause the clinical symptoms, which are subsequently used to classify the symptoms as a "disease." Analyzing the disease course longitudinally reveals several distinct steps during disease progression, for which the presence of biomarkers is of importance, both for identification of disease status and for prediction of disease course and treatment options. However, biomarkers per se are not always available today. We have chosen here to discuss disease characteristics and potential biomarkers in one common chronic inflammatory disease, rheumatoid arthritis (RA), which affects approximately 0.5 to 1% of the population worldwide. In this chapter we focus on the following factors:

1. Onset of disease in order to discuss the questions in whom and why the disease occurs, and whether and how onset can be predicted

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

from biomarkers that are present before the occurrence of clinical symptoms

2. Progression of disease with respect to development of joint destruction, but also other with respect to complications such as extra-articular manifestations, cardiovascular events, and lymphoma development in this patient group
3. Treatment of the individual patient and of specific symptoms and disease manifestations
4. Selection of patients in clinical trials of new drugs

## RHEUMATOID ARTHRITIS DISEASE PROCESS

Rheumatoid arthritis (RA) is a disease defined by seven criteria, with four that should be fulfilled to make the diagnosis (Table 1). These criteria have been useful in harmonizing clinical trials and clinical practice. However, they are not based on what is now known about etiology or pathogenesis, and they are not too helpful in selecting treatment for the single patient. Hence, there are needs to redefine the diagnosis for RA and related diseases, first to define entities more related to distinct etiologies and pathogenetic mechanisms, then to use such new entities for stratification and selection of patients in clinical trials and clinical practice.

Basic features of the immune and inflammatory process in RA are, on the one hand, processes that can be identified in the peripheral circulation, initially

**TABLE 1 Classification Criteria for Rheumatoid Arthritis**[a]

1. Morning stiffness in and around joints lasting at least 1 hour before maximal improvement
2. Soft tissue swelling (arthritis) of three or more joint areas observed by a physician
3. Swelling (arthritis) of the proximal interphalangeal, metacarpophalangeal, or wrist joints
4. Symmetric swelling (arthritis)
5. Rheumatoid nodules
6. Presence of rheumatoid factor
7. Radiographic erosions and/or periarticular osteopenia in hand and/or wrist joints

*Source:* Arnett FC, Edworthy SM, Bloch DA, et al. (American Rheumatism Association) (1988). The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis. *Arthritis Rheum*, 31:315–324.

[a]Criteria 1 through 4 must have been present for at least six weeks. Rheumatoid arthritis is defined by the presence of four or more criteria, and no further qualifications (classic, definite, or probable) or list of exclusions are required. These criteria demonstrated 91 to 94% sensitivity and 89% specificity for RA compared with non-RA rheumatic disease control subjects.

**Figure 1** Inflamed RA joint. In healthy joints a thin synovial membrane lines the joint capsule and the synovial fluid. In the RA joint both the synovial membrane and the synovial fluid are infiltrated by inflammatory cells, leading to tender and swollen joints. The synovial membrane also "grows" over the cartilage, aiding in the process of cartilage and bone desctruction.

rheumatoid factors (RFs), and on the other hand, processes in the inflamed tissue, mainly the joints (Figure 1). Rheumatoid factors, identified almost 70 years ago, are part of the diagnostic criteria for RA. Being present in some 50 to 60% on incident RA cases and increasing over time with active disease, these auto-antibodies are also seen in many non-RA conditions and are thus not very specific for the disease.

Rheumatoid factors have never been shown to be pathogenic by themselves, neither in patients nor in experimental models. They are thus seen mainly as biomarkers of importance for diagnosis and prognosis of a more severe disease course, but not necessarily directly involved in disease pathogenesis. Joint inflammation in RA is focused on synovial inflammation, in many cases associated with cartilage destruction and concomitant erosions in bone. This inflammation has been studied in large detail over the years, demonstrating that its features are common to many other types of chronic inflammation in other tissues. No real RA pathognomonic features have yet been identified, the most unique feature identified so far being the way the inflammatory cells and molecules attack and destroy bone and cartilage.

Having the major features of RA, the synovial joint inflammation and presence of RF being typical but by no means unique for RA, there is an obvious need to define more specific features of the disease. The identification of such features would enable us to search for a better understanding of the pathogenesis of RA, a more accurate diagnosis based on biomarkers, and more specific treatments.

## STUDIES ON ETIOLOGY AND PATHOGENESIS AS A BASIS FOR DEVELOPMENT OF BIOMARKERS FOR DIAGNOSIS AND PROGNOSIS IN RA

Any understanding of a complex, partly genetic disease is based on an understanding of how genes and environment interact in giving risk to immune reactions that contribute to the joint destruction and other inflammatory reactions in RA. In healthy subjects, the major role for the immune system and subsequent inflammatory reactions is to defend us against pathogens, but in RA the immune system has partly changed focus to attack our own tissues, primarily the joints, and is thus denoted as an autoimmune disease.

### Genes

There is strong evidence to support a significant genetic component to the susceptibility of RA. Twin studies clearly demonstrate an overrepresentation of disease concordance in monozygotic twins (12 to 20%, depending on study) compared to dizygotic twins (4 to 5%) and the general population (0.5 to 1%). Analysis on the gene level demonstrates the strongest genetic association with genes within the HLA region, specifically the *HLA-DRB1* gene. Its gene products, the MHC class II molecules, were described in the 1970s to be present on cells in the inflamed joint, allowing antigens (part of proteins, generally pathogens, but in autoimmune diseases self-proteins) to be presented to the immune system and subsequently to trigger inflammatory reactions (Figure 2). Serologic and later genetic typing of the various MHC molecules revealed that a few allotypes of *HLA-DRB1* were overrepresented in RA patients. A closer analysis demonstrated even identical amino acid

**Figure 2** Inflammatory cells in the RA joint. A number of immune cells have infiltrated the joint and local production of inflammatory mediators, including cytokines and antibodies, occurs. The synovial fluid, which functions as a cushion during joint movements, is in a healthy joint acellular. Illustrated to the left is the presentation of an antigen by the dendritic cell to a T-cell; the yellow connector is a MHC class II molecule. Cytokines, released from the immune cells, function as signaling molecules between cells. (*See insert for color reproduction of the figure.*)

sequences in those regions of the MHC class II DRβ1 chain, which are in contact with the antigen and the T-cell receptor on the T-cell mediating the specific immune responses. This amino acid sequence is termed *shared epitope*. The nature of the specific immune reactions mediated by the MHC class II molecules has, however, been surprisingly difficult to define. Identifying the specific antigens would help to identify the autoimmune trigger and make it possible to interfere specifically to break the autoimmune reactions. In total, the HLA region contributes 30 to 50% of the genetic component for RA in Caucasians. It appears that other MHC class II genes and allotypes may contribute to RA in other ethnic groups, and much is still not known about the contributions of different genes and allotypes within the MHC concerning susceptibility and disease course in RA.

Only much more recently, a second genetic risk allele has been identified in populations of European descent. This minor allele of a nonsynonomous single-nucleotide polymorphism (SNP) in the protein tyrosine phosphatase nonreceptor 22 (*PTPN22*) gene confers the second-largest genetic risk to the development of RA, with an odds ratio of about 1.8. *PTPN22* encodes the intracellular protein lymphoid tyrosine phosphatase, which plays a central role in immune responses by playing an integral part in signal transduction and T-cell receptor signaling pathway and inhibiting T-cell activation. This variant was first demonstrated for type 1 diabetes, but was soon confirmed in a number of autoimmune diseases, including RA, systemic lupus erythematosus (SLE), and Grave disease. However, other autoimmune diseases show no association with this SNP, suggesting subsets of autoimmune diseases to be defined accordingly.

The recent introduction of whole genome-wide association studies allowed, for the first time, good coverage of common variations in the human genome. Hundreds of thousands of SNPs in thousands of samples were genotyped and compared. Interestingly, studies focusing on RA again demonstrated the strongest effects for the two well-documented RA susceptibility genes *HLA-DRB1* and *PTPN22*. Other genes (Table 2) make a more modest contribution to susceptibility. Future studies have to identify remaining, probably smaller, genetic effects and how all the genetic effects interact with each other as well as with environmental factors in inducing and perpetuating the disease.

**TABLE 2 Contribution of Genetic Risk Factors in Rheumatoid Arthritis**

| Gene | Odds Ratio |
|---|---|
| *HLA* | 6.4 |
| *PTPN22* | 1.8 |
| *6q23* | 1.2 |
| *STAT4* | 1.2–1.4 |
| *TRAF1/C5* | 1.1–1.4 |

## Environment

Information on environmental factors important for the development, perpetuation, or course of RA is surprisingly scarce. Smoking is the only conventional environmental factor that has been linked reproducibly to an increased risk of developing RA. Other exposures, such as silica dust and mineral oils, have been reported in a few studies. It has not yet been possible to verify frequently hypothesized stimuli such as microbial infections with the methods used to date. Smoking was initially considered as an unspecific risk factor, of interest mainly from a public health perspective. However, newer studies indicate that smoking is a specific trigger of RA, as discussed in more detail below.

## Immunity

Studies on specific immune reactions in RA have been confined almost entirely to those involving autoantibodies. As described above, they were initially restricted to the measure of rheumatoid factors, but more recently, antibodies specific for citrullinated proteins have been shown to be of great importance. This is discussed in detail below, since their presence covariates with genetic and environmental factors, providing an important tool in subgrouping patients into different entities of RA. In the process of joint inflammation and cartilage and bone destruction, many different cells and molecules of the immune system participate. Some of them are illustrated in Figure 2. However, even if some of these inflammatory processes are revealed in detail, a specific trigger has still not been identified.

In recent years, advances within the field of cytokine regulation and cytokine-directed therapy have largely dominated the research field of RA, illustrating how therapeutic progress is possible even though the role of adaptive immunity in the disease is not fully understood. Cytokines are soluble molecules that mediate the communication between cells of the immune system but also with other cells of the body, such as the endothelium. Interestingly, the first cytokine that was targeted, tumor necrosis factor (TNF), belongs to the innate immune system. Blocking IL-1, another cytokine belonging to the innate immune system, has not proven to be as effective as TNF blockade for the majority of the RA patients. Recent clinical trails blocking a third cytokine in this family, IL-6, show promising results. This cytokine exerts effects within both the innate and the adaptive immune systems.

Temporarily eliminating B-cells, which are the producers of antibodies, has also proven a successful therapy. A third alternative, blocking the interaction between cells presenting antigens and T-cells, has resulted in an approved therapy. Together, these treatment-based data also demonstrate the significant role of the various parts of the innate as well as adaptive immune system for disease progression.

### Citrulline Immunity

The presence of antibodies specifically identifying citrullinated antigens, specifically termed *antibodies to citrullinated protein antigens* (ACPAs) are a strong predictor of developing RA. Approximately 60% of all RA patients carry such antibodies. These antibodies are highly specific for the disease; that is, they are rare in the normal population (<2%) and are also quite rare in other inflammatory conditions. Almost all patients who carry ACPAs developed them before disease onset. ACPAs are directed against proteins, which as the name implicates, contain the amino acid citrulline. Citrulline occurs only upon posttranslational modification of the amino acid arginine by enzymatic conversion. Even if these auto-antibodies are more specific for RA than for RF, it is important to ask the question if their presence is an epiphenomenon or is causally related to the disease. This helps in further dissection of the pathophysiology of the disease and in the development of new treatments. Here, animal models provide a tool to test the hypothesis of citrullination to be causative of the disease. One example is arthritis induced in the rat by immunization with collagen type II, a protein expressed almost exclusively in the joint. Immunization with the citrullinated form of collagen type II resulted in a more severe arthritis than immunization with the same noncitrullinated protein. In a mouse model, where transfer of antibodies directed toward collagen induces a mild arthritis, the addition of antibodies directed against citrullinated fibrinogen enhanced the arthritis. Thus, in experimental arthritis models citrullination can change the immunogenicity of self-antigens, and some citrullinated proteins may contribute to arthritis development.

From the data above we can conclude that immunity to citrullinated proteins may play a pathogenic role in a subset of RA patients; however, so far we have not identified the specific proteins that are targeted by the immune system. How do we then measure ACPAs? Test kits have been developed which contain cyclic citrullinated peptides (CCPs), where the amino acid citrulline is flanked by a variety of amino acids to mimic many different peptide sequences. Thus, the test measures anti-CCP antibodies, and this is what is generally reported in patient files. In summary, the presence of ACPAs in the circulation is more predictive for RA than high blood pressure is for cardiovascular disease and thus can be considered as a biomarker for a subset of RA patients.

## BETTER DIAGNOSIS BY MEANS OF BIOMARKERS AND GENETICS

By the late 1970s, the MHC class II genes were already identified as a major genetic risk factor for RA. However, only the presence of specific MHC class II alleles does not result in RA, since the disease-associated *HLA-DRB1* alleles are common also in healthy subjects. But combining genetic studies

with ACPA analysis, the genetic association of RA to *HLA-DRB1* SE has recently been shown to be confined entirely to the ACPA-positive subset of RA. In contrast, ACPA-negative RA may be associated with a unrelated *HLA-DR* allele, HLA-DR3. Also a second major genetic risk factor for RA, the polymorphism in the *PTPN22* gene was also shown to be associated only with the ACPA-positive disease.

In contrast, other genetic risk factors, in particular variations in the interferon regulating factor 5 (IRF-5), but also polymorphisms in a newly identified risk gene in the C-type lectin complex, were associated exclusively with ACPA-negative disease. Taken together, the descriptive studies of disease course and genetic linkages strongly indicate that ACPA reactivity splits RA into two major and clinically relevant subsets of disease and thus becomes an important biomarker for one subgroup of RA. Practically, ACPA-positive and ACPA-negative RA should be treated as separate entities when studying the molecular pathophysiology of RA and probably also when selecting treatment for some treatments for the single patient (Figure 3).

Including smoking habits in these combined analyses provides an even clearer risk assessment for developing RA. The relative risk of developing ACPA-positive RA was shown to be over 20 times higher for smokers carrying two copies of the *HLA-DRB1* SE alleles than for nonsmokers with no SE alleles. On the other hand, no increased risk was discerned from smoking concerning development of ACPA-negative RA. This leads directly to the question of whether smoking can trigger an ACPA immunity. Recent studies suggest that this could be the case since cells from bronchoalveolar lavage from smokers, but not from nonsmokers, contain large amounts of citrullinated proteins, and smoking can activate macrophages and thus enhance their antigen-presenting capacity.

The disease onset of RA can be gradual, and thus patients can have swollen and tender joints without being given the diagnosis RA, which is based on

**Figure 3** Rheumatoid arthritis is a multifactorial disease. A number of predisease factors have been identified, which are of importance for the later disease course but not enough to initiate clinical disease. However, the trigger for clinical disease onset has still not been identified. The presence or absence of anticitrulline protein antibodies (ACPAs) distinguishes two forms of RA. Some patients will have swollen and tender joints but not fulfill four of the seven criteria for RA and thus carry an unspecific arthritis.

achieving four of seven specific criteria. These patients are classified as *undifferentiated arthritis* (UA), having an inflammatory arthritis for which no specific diagnosis can be made. An important question is if these patients should be treated in order to ameliorate disease progression to RA and retard radiographic joint damage or even prevent the development of RA in these patients. A recent double-blind, placebo-controlled, randomized clinical trial indicated that methotrexate (MTX) treatment as used for RA patients can postpone progression to RA and retard radiographic progression but not prevent the development of RA from UA. Subgroup analysis revealed that the beneficial outcome was most pronounced in patients with anti-CCP antibodies. In contrast, in the anti-CCP-negative subgroup the effect of MTX on the development of RA, the radiographic progression, and even the signs and symptoms was not demonstrable. Thus, this study provides evidence of distinguishing between anti CCP-positive and CCP-negative arthritis, even before the diagnosis RA is met, and therefore also becomes an important biomarker for undifferentiated arthritis.

The identification of predisease biomarkers might in the future lead to treatments which can be given to healthy subjects before the clinical diagnosis of RA and so prevent disease onset. An example already applied in medicine is the treatment of high blood pressure to prevent cardiovascular disease.

## BETTER PROGNOSTIC TOOLS WITH THE HELP OF BIOMARKERS AND GENETICS

Rheumatoid arthritis affects not only joints but also possibly, inflammation in other organs. Manifestations include rheumatoid nodules, secondary Sjögrens syndrome, rheumatoid lung disease, pleuritis, pericarditis, vasculitis, neuropathy, Felty syndrome, and severe eye disease, and are commonly summarized as extraarticular manifestations. Different co-morbidities also occur during the disease course. Cardiovascular morbidity and mortality occur at rates greater than would be expected from the profile of established risk factors. The average risk of lymphoma is increased in RA; however, a more detailed analysis indicates that the risk is increased primarily in patients with the most severe disease (Figure 4).

### Extraarticular Disease Manifestations

Extraarticular disease manifestations are more likely to occur in patients with more severe joint disease. Rheumatoid nodules often precede the onset of severe RA and thus can be considered a biomarker for severe disease. Also, their clustering with all different extraarticular manifestations indicate that vascular pathogenetic mechanisms are important in all types of extraarticular RA. This is of particular interest given the association of RA with cardiovascular co-morbidity. The different manifestations tend to cluster in specific

**Figure 4** Inflammatory burden. With increased accumulated inflammatory burden the risk for additional disease states and complications increases for patients with RA. It is thus of importance to control the inflammation at all time points, a difficult task when not all patients respond to the antirheumatic therapies available today.

patterns and suggest shared disease mechanisms in these systemic manifestations. There are very likely several genetic and environmental factors affecting the development of these manifestations, of which some are described below.

An association of *HLA-C3* with vasculitis has been described. *HLA-C3* is the product of a specific MHC class I gene and thus with CD8+ cytotoxic T-cells and NK-cells, in contrast to MHC class II proteins, which interact with CD4+ T-helper cells. Smoking is an independent predictor of vasculitis and is probably involved in vascular damage by antigen modification as described above. The increased number of patients with specific autoantibodies such as RF and ANAs (antinuclear antibodies) supports a role for immune complexes in the pathogenesis of vasculitis, which in turn indicates B-cell abnormalities in the development of extraarticular RA.

In summary, extraarticular manifestation indicate a more severe disease; however, this risk group is today not routinely analyzed early in the disease course. Here, specific biomarkers could possibly aid an early aggressive treatment of this patient group in order to limit the progression of extraarticular manifestations.

## Cardiovascular Disease in RA

Cardiovascular (CV) morbidity and mortality in RA occur at rates greater than would be expected from the profile of established CV risk factors. Diabetes mellitus, hypercholesterolemia, hypertension, cigarette smoking, and obesity are generally powerful classifiers of CV risk and when comparing the profiles of these risk factors in people with and without RA, they are similar. Thus, there must be RA-specific factors explaining the increased risk. Dividing the patients in younger and older patients demonstrates that such factors are more common in the younger age group. In older patients, the

proportion of atherosclerosis can be explained by established CV risk factors as described above. In contrast, in the younger age group, systemic inflammation seems to exert its atherosclerotic effects early. High-resolution carotid ultrasound is used to measure carotid intima media thickness (IMT). These measures may thus be used as a biomarker of subclinical atherosclerosis. Interaction calculations suggest that the ESR's effect on IMT varies according to the number of CV risk factors; thus, higher ESR values, a measure for inflammation, are associated with greater IMT only in the presence of CV risk factors. In patients without CV risk factors, the ESR is not associated significantly with IMT.

Taking genetic and environmental components into consideration of CV disease in RA patients demonstrates that the presence of two SE alleles predicts death from cardiovascular disease in RA patients, and this is independent from autoantibody status. However, the greatest risk of death from CV disease is associated with an interaction among smoking, SE alleles, and anti-CCP antibodies. Interestingly, no association of the *PTPN22 gene* with mortality was detected.

In summary, both established CV risk factors and RA manifestations account for a significant proportion of atherosclerosis is RA. Factors related to RA may have a greater influence on the extent of atherosclerosis in young patients. The presence of established risk factors may be necessary for systemic inflammation to promote atherosclerosis; however, more studies are needed to understand these interactions.

## Lymphoma in RA

Among RA patients there is in general a doubled risk for lymphoma. However, a closer analysis of disease severity, as measured by degree of joint destruction, ESR, number of affected joints, and accumulated inflammatory load, revealed a more pronounced relative risk in patients with the most severe disease and little or no increase in those with mild to moderate disease. This raises the question of whether lymphomas arise as a consequence of treatment or because of a lack thereof. Larger cohort studies have thus far not confirmed any treatment-related excess of lymphoma in general. However, it is premature to make firm conclusions about the true lymphoma risk in patients treated with TNF antagonists. In summary, the data so far indicate that the inflammatory burden should be kept as low as possible to possibly reduce the risk for lymphoma development.

## Cartilage and Bone Destruction

During the inflammation in the joint, cartilage and underlying bone are broken down. Matrix metalloproteinases (MMPs) are enzymes active in this process, which results in the release of a number of collagenous and noncollageneous cartilage and bone-derived molecules. Serum levels of MMP-3 and urinary

levels of c-telopepetide of collagen type II (CTX II) have been identified as two independent baseline factors that predict radiographic progression. Upon successful MTX treatment, MMP-3 levels decrease. Also, serum cartilage oligomeric matrix protein (COMP) levels are predictive of radiographic damage. Proof-of-concept studies demonstrate that targeting RANK-mediated osteoclastogenesis prevents inflammatory bone loss, and clinical application has only just begun by blocking RANKL.

Replacing radiographic measures with measures of biochemical molecules in serum and/or urinary samples might in the future become the preferred way to measure joint destruction specifically. Traditionally, high inflammatory burden and measures of CRP have been included in the prediction of joint destruction, but the concomitant measures of inflammation and joint destruction indicate that the inflammatory and destructive processes are uncoupled and therefore need to be identified and treated separately.

## BIOMARKERS PROVING LEADS CONCERNING EFFECTS OF TREATMENT OF RA

The drugs used in the treatment of RA are generally divided into three groups: nonsteroidal anti-inflammatory drugs (NSAIDs) to relieve pain, traditional disease-modifying antirheumatic drugs (DMARDs), and biologics. There are today some general guidelines for the treatment of RA; however, biomarkers guiding the most adequate selection for the single patient are missing.

In the majority of RA patients, treatment with methotrexate or other DMARDs only partly reduces clinical and radiological progression of the disease. For many patients, therefore, the introduction of the biological drugs provided a major breakthrough. By blocking the proinflammatory cytokine TNF, joint progression could be halted much more efficiently than before in a large group of patients. More recent drugs eliminating circulating B-cells or blocking co-stimulation of T-cells also indicate a slowdown in joint destruction. Measuring levels of TNF in the inflamed tissue has been suggested to be a biomarker for treatment response to TNF blocking agents. Unfortunately, it has yet been possible to describe such a marker for serum samples.

With the identification of the association of smoking, SE alleles, and anti-CCP antibodies with the greatest risk of death from CVD, it will be possible to be more active in treatment to prevent cardiovascular disease in these patients at high risk for CV disease. In the treatment of lymphoma, which in the majority of cases are B-cell derived, a specific treatment option exists for RA patients. Rituximab was established in 1998 as a drug to treat patients with B-cell lymphomas, and the indication was extended in 2006 to treat patients with moderate to severe RA, independent of lymphoma associations. Thus, in these cases both the lymphoma and the RA are treated with the same drug.

## CONCLUDING REMARKS

In summary, RA is a heterogeneous disease with regard to severity of the joint inflammation and other inflammatory manifestations. To prevent disease onset or progression of disease in the single patient, distinct biomarkers are needed, and only a few have yet been identified. The fact that the presence or absence of ACPAs divides the disease into two distinct entities will very likely influence future treatments and clinical trials. Clinical trials, if not already focusing on a subgroup of patients, need also to be adequately powered to allow subgrouping patients according to genetic setup, environmental exposures, and different nonsynovial inflammations in order to find biomarkers for individualized therapies. Today's and tomorrow's biological therapies targeting different parts of the immune and inflammatory pathways will also increase our understanding of disease etiology and progression and help identify new drugs.

## INTRODUCTION

The importance of a biomarker in drug development is based on the weight of evidence that changes in dose and/or drug concentration levels correlate strongly with the biomarker and the clinical outcome desired. The linkage between pharmacokinetics of a new chemical entity (NCE), the dynamics of a biomarker, and the ultimate clinical outcome should be based on robust theoretical considerations, prior therapeutic experience, well-understood pathophysiology, and knowledge of the drug's mechanism of action. The validation of biomarkers is therefore very important, particularly if one considers their relevance for decision-making and regulatory purposes. The elements described below are crucial for the integration of a biomarker in a drug development program.

1. *Identification, quantitation, and validation of biomarker assays and drug concentrations.* Reliable and selective assays should be validated under

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

a good laboratory practices (GLP)–like environment for quantitative methods for measuring both biomarker responses and drug concentrations. Most biomarkers are endogenous macromolecules that can be measured in biological fluids. As for drug assays, biomarker assays should provide acceptable sensitivity, specificity, precision, and accuracy. For example, intra- and intersubject variability of the biomarker should be minimal and well understood, biomarker stability and sample storage conditions should be controlled, and quantitative assay should be standardized and validated with adequate power to distinguish between treatment and control groups [1–3].

Assays should be validated to meet study objectives at various drug development stages and possess adequate performance to quantify biochemical responses specific to the target disease progression and drug intervention. In addition, biomarker measurement should be technically practical, so that measurement can be obtained by minimally invasive techniques and that the sampling of the biomarker is minimal or is taken at the same time as other physiological, safety, or efficacy measurements [4].

2. *PK/PD correlation and integration of model-based drug development.* Biomarkers typically have different time courses from clinical endpoints and often are more directly related to the time course of drug concentrations. To evaluate potential correlations, adequate information should be available on the pharmacokinetics (PK) of the new chemical entity (NCE). Similarly, adequate information should be available on the pharmacodynamics (PD) (including PK) of the biomarker, with the expected effect on clinical outcome. Following the identification of correlations between the NCE and specific biomarkers, PK/PD modeling may be performed in early stages of drug development to gain greater insight into the effect of drug concentrations on the biomarker as a function of time. PK/PD modeling involves a set of techniques using mathematical and mechanistic (as opposed to empirical) models derived from quantitative pharmacology. Biomarkers, together with PK/PD modeling and simulation, provide a continuous process to link what has been learned from today's drug development cycle to the next generation of biomarkers, assays, and models [5–7].

3. *Correlation between biomarkers and clinical endpoint.* The availability of a validated biomarker for a specific clinical endpoint may greatly facilitate the development of compounds that act via well-understood mechanisms of action. For example, biomarkers for HIV and AIDS include viral load (the number of free virus particles in the blood) and the count of CD4+ immune system cells. Fasting blood sugar and hemoglobin A1c, a protein that indicates a patient's blood sugar history, are established biomarkers for diabetes treatments. The relationship of the biomarker to the therapeutic endpoint should

be validated in early phase II trials; and, when possible, as early as phase I [8,9].

Many surrogate markers can be assessed in healthy volunteers and in the intended patient population. The ability to assess surrogate markers in healthy volunteers can bring the initial decision-making process into phase I rather than phase II or phase III of the NCE development process. This can be a significant competitive advantage to those who use the opportunity. Table 1 presents widely used biomarkers according to disease and indications. Biomarkers can be elevated to the status of a surrogate endpoint based on the

**TABLE 1 Widely Used Biomarkers for Specific Disease or Indications**

| Biomarkers | Disease or Indication |
|---|---|
| Pulmonary function tests, forced expiratory volume (FEV) | Asthma |
| PT (including INR), APTT, anti-Xa activity, fragment 1 + 2, plasminogen, plasmin inhibitor, D-dimer | Coagulation and fibrinolysis |
| Leukotrienes, cytokines, and chemokines | Chronic obstructive pulmonary disease |
| Epidermal growth factor (EGF), fibroblast growth factor (FGF), human growth hormone (HGH), neopterin | Growth modulation |
| Viral load, CD4 count | HIV |
| Cortisol, estradiol, estrone, follicle-stimulating hormone, luteinizing hormone, progesterone, testosterone | Hormonal control |
| Angiotensin-I, angiotensin-II, plasma renin, aldosterone, and angiotensin-converting enzyme (ACE) activity | Hypertension |
| Eicosanoids (prostaglandins and leukotrienes) | Inflammation |
| Interferons, interleukins, tumor necrosis factor (TNF), rheumatoid factor | Immune modulation, rheumatoid arthritis |
| Cholesterol, fatty acids, HDL, LDL, phospholipids | Lipid metabolism |
| Cytidine deaminase activity, inosine, xanthine, hypoxanthine, uric acid | Nucleotide metabolism |
| 8-Hydroxy-dG, protein carbonyls, I-κB, NF-κB | Oxidative stress (diabetes, heart disease, arthritis, obesity, and cancer) |
| Glucose, glucagon, fructosamine, glycosylated albumin, and hemoglobin A1c, insulin, C-peptide | Type 1 and 2 diabetes mellitus |
| Stomach fullness, cholecystokinin, glucagon-like peptide 1, bombesin, somatostatin, ghrelin, leptin, glucose, insulin, diet-induced thermogenesis, temperature, ventilatory parameters | Satiety and satiation |
| ProMMP-1, ProMMP-3, tissue inhibitory of MMP-1 | Tissue remodeling |

weight of evidence that demonstrates that changes in the biomarker correlate strongly with the desired clinical outcome. The best known physiologic surrogate marker is blood pressure reduction as an indicator of reduced incidence of stroke and myocardial infarction. This surrogate marker is now used as a clinical endpoint, because a strong relationship between reduction in blood pressure and a reduction in the incidence of myocardial infarctions and strokes has previously been established.

For innovative products, limited information may be available on the relationship between the PK of a drug, the effect on a candidate biomarker, and the ultimate clinical response. Although this may limit the use of predetermined biomarkers in the early development phases of a drug, the incorporation of recent advances in genomics, pharmacogenetics, and proteomics may help to qualify various candidate biomarkers. Pilot exploratory studies should therefore be conducted to qualify and validate candidate biomarkers for predictive clinical assessment of disease progression and the effect of drug intervention. Mechanistic approaches using new technological advances in target validation, functional biology, proteomics, genomics, and the monitoring of gene expression using DNA arrays, imaging, and the correlation of these effects to the disease state may hold promise for an earlier understanding of disease and toxicological processes, improve the predictiveness of preclinical pharmacology and toxicology data to humans, and find suitable biomarkers for use in the early stage of drug development of innovative products [2,10].

The appropriate combination of biomarker identification and selection, bioanalytical methods development and validation for drugs and biomarkers, and mechanism-based PK/PD models for fitting data and predicting future clinical endpoints and outcomes may provide powerful insights and guidance for effective drug development, toward safe and efficacious medicine for individual patients [6–8,11,12]. The U.S. Food and Drug Administration (FDA) is developing these concepts as part of its *critical path initiative*, where the agency recognizes that the major contributor to inefficiency in development was the absence of innovative new methods for preclinical and clinical testing of drugs. The FDA recommended new tools and various opportunities to improve drug development, including the use of validated biomarkers and the application of model-based drug development (MBDD). In the following sections we focus on the PK/PD correlation assessment of a drug and a biomarker, and the use of PK/PD modeling and simulation to optimize drug development and decision making.

## PK/PD CORRELATION OF BIOMARKERS

Plans to incorporate biomarkers for potential correlations in drug development programs should occur when a new candidate molecule is being identified and the discovery process is starting. To evaluate potential correlations between the drug and candidate biomarkers, adequate information should be

available on the PK of the drug. Preliminary PK/PD correlation analyses may be performed using noncompartmental approaches (i.e., model independent) by deriving parameters such as the area under the concentration–time curve (AUC), maximum concentration ($C_{max}$), time to maximum plasma concentrations ($t_{max}$), and terminal elimination half-life ($t_{1/2}$). Exploratory data analyses (EDAs) between drug exposure data and candidate biomarkers are typically performed by plotting individual concentration data and/or PK parameters of the drug versus the candidate biomarker using appropriate data transformations and in appropriate subgroups (e.g., by gender, dose, or route of administration) in order to identify the impact of drug exposure on the source and magnitude of variability in biomarker response. During exploratory data analyses, questions in Table 2 should be answered to perform PK/PD correlations of biomarkers.

In the simplest case, biomarkers will be related directly to the drug concentrations in the biological fluid sampled; that is, the biomarker will respond in a graded fashion so that increasing drug concentrations will result in a gradual increase or decrease in the biomarker of interest over time. A temporal relationship between the time course of drug concentrations and the biomarker is observed. In some cases, the temporal delay may only be a few minutes to an hour, whereas in other cases it may be as long as several hours to days. Exploratory analyses may also provide valuable information on the pharmacodynamics of biomarkers as well as PK/PD correlations as presented in Table 3.

Preclinical and clinical study designs should provide as much information on the nature of the PD response of candidate biomarkers. Depending on the PK of the drug and the dynamics of the biomarker, exploratory PK/PD correlations may be limited and likely to require a more mechanistic approach for an optimal assessment of PK/PD correlations. Mechanism-based PK/PD

**TABLE 2 Pharmacokinetic Properties and Impact on PK/PD Assessment**

| Pharmacokinetic Property | Impact on Correlation Assessment |
|---|---|
| Absorption | Will rate and/or extent of drug exposure correlate with biomarkers? Is a minimum threshold likely to correlate with biomarker response? |
| Distribution | Will total (unbound plus bound) or unbound drug levels contribute to the overall effect on biomarkers? Are concentration levels in peripheral tissues likely to correlate with biomarkers? |
| Metabolism | Will active metabolites contribute to the overall effect on biomarkers? Is there a temporal delay between concentrations and biomarkers (proteresis or hysteresis)? |
| Elimination | Will the rate of elimination of the drug correlate with biomarker response? Does drug elimination parallel the biomarker response? |

**TABLE 3 Pharmacodynamic Properties and Impact on PK/PD Assessment**

| Pharmacodynamic Property | Impact on Correlations Assessment |
|---|---|
| Mechanism of action | Will the drug stimulate or inhibit the formation or degradation of the biomarker? Will the drug create a reversible or irreversible effect on the biomarker? |
| Competitive ligands | Will the drug compete with endogenous, environmental, or dietary ligands for receptor binding? |
| Diurnal variation | Are placebo data available to determine a diurnal/circadian cycle of biomarkers? |
| Disease state | Will the disease state affect the biomarker response? Does drug elimination parallel the biomarker response? |

models differ from empirical descriptive models in that they contain specific expressions to characterize processes on the causal path between drug administration and effect [13–15]. In the next section we focus on important issues and concepts that apply to PK/PD modeling and the use of biomarkers to improve drug development processes.

## PK/PD Modeling of Biomarkers

PK/PD modeling and simulation tools have continued to develop to a high level of sophistication over the past 20 years. Mechanism-based PK/PD modeling involves a set of techniques using mathematical and mechanistic models derived from quantitative pharmacology. The simplest compartmental PK model can be described as a one-compartment model following intravenous administration of a drug. A schematic representation of the compartmental model is presented in Figure 1. In this example, the removal of

| PK Model | Equation | Pharmacokinetics |
|---|---|---|
|   | $C_{\text{time}} = \frac{\text{dose}}{Vc} \bullet \exp^{-K_{10} \bullet \text{time}}$ |   |

**Figure 1** Pharmacokinetic modeling and equations.

drug from the central compartment (i.e., systemic circulation) was described using a first-order elimination rate constant. Compartmental analyses can be performed routinely by fitting the data to a model using a PK/PD software package such as WinNonlin (Pharsight, a Certara Company, St. Louis, Missouri), Kinetica (ThermoFisher, Waltham, Massachusetts), S-ADAPT (University of Southern California,) or NONMEM (University of California at San Francisco). The PK of drugs can be described using more advanced compartmental models and can be customized to describe any type of PK behavior. Case studies in which different types of compartmental models were used in preclinical and clinical drug development are presented later in the chapter.

Modeling the concentration–effect relationship on the biomarker is very dependent on the mechanism of action of the drug. In vitro studies that may elucidate this mechanism are very important in the early stage of drug development. For example, drug-induced changes in biomarkers of interest are often modeled using classical drug receptor theory following the law of mass action. This theory predicts that as receptors in the target organ interact with the drug, the biomarker levels will increase with increasing interaction until all receptors have been occupied, at which time no further change in biomarker will occur. In its simplest form, the effect on the biomarker will be driven by the measured drug concentration over time, $C_{\text{time}}$, assuming that drug concentrations in the systemic circulation is at equilibrium with the effect site. The classic and most commonly used PD model under these conditions is the $E_{\max}$ model, which is an empirical function for describing nonlinear concentration–effect relationships. It has the general form illustrated in Figure 2, where $E_{\max}$ represents the maximum effect on the biomarker, $C_{\text{time}}$ the concentrations of a drug predicted over time with a PK model, and $EC_{50}$ the concentration of the drug that produces half of $E_{\max}$. The PD model can be

| Equation | Pharmacodynamics |
|---|---|
| $\text{Effect}_c = \text{E}_{\max} \bullet \dfrac{C^n_{\text{time}}}{C^n_{\text{time}} + EC^n_{50}}$ |  |

**Figure 2** Pharmacodynamic modeling and equations.

**Figure 3** Pharmacokinetic/pharmacodynamic modeling.

related to receptor theory, where $EC_{50}$ is the parameter characterizing the potency of the drug on the biomarker and $n$ is a sigmoidicity factor describing the drug concentration vs. the effect on the biomarkers or the number of molecules interacting at the biomarker receptor. Although the $E_{max}$ model is highly versatile for different situations, more sophisticated PD models have been developed over the last decades.

PK/PD modeling builds the bridge between these two classical disciplines of pharmacology, as depicted in Figure 3. PK/PD modeling is performed to gain greater insight into how drug concentrations may affect the biomarker as well as how the models can be used to perform simulations in order to predict changes in biomarker levels under a variety of experimental conditions. Models can improve the prediction and assessment of patient response with the use of simulations, and therefore increase the success of a drug development program [13–15]. For example, the models can be used to refine a dosing regimen in order to predict the drug exposure (PK modeling) and the resulting effect on the biomarker, to guide starting doses and regimens (as well as adjustments of dosage or dosing regimens in special populations), and to provide a better understanding of outcomes from clinical efficacy studies. Case studies will be presented to demonstrates how biomarkers, together with PK/PD modeling and simulation, provide a continuous process to link what has been learned from today's drug development cycle to the next generation of biomarkers, assays, and models.

## Critical Path Initiative

In the current health care environment, dominated by increasing expenses associated with drug development programs, rapidly changing technologies, generic competition, and therapeutic substitution, there is increased pressure to develop new therapies using effective drug development programs. The escalating costs and low productivity of drug development have been well documented over the past several years. In March 2004, the FDA recognized that drug development has become increasingly challenging, inefficient, and costly [16]. The agency concluded that the major contributor to the inefficiency in development was the absence of innovative new methods for preclinical and clinical testing of drugs. In its critical path initiative, the agency called upon new, publicly available scientific and technical tools to improve drug development programs. These include the use of biomarkers and clinical trial endpoints as well as PK/PD modeling to improve decision making and make the development process more effective and more likely to result in safe products to benefit patients [17–20].

The agency recommended reviewing the body of collective biomarker information to build a new framework for biomarker and surrogate endpoint use in drug development [16]. Part of this initiative is to complete an inventory of surrogate endpoints that have been used for past drug approvals and to evaluate how the decision was made to accept the respective surrogates. As part of this process there will be an attempt to identify widely used, disease-specific biomarkers and determine the gap that exists to elevate these biomarkers to surrogate endpoints. The acceptance of CD4 cell counts and HIV plasma RNA as mechanism-based surrogate endpoints are probably the best examples. The elevation of a biomarker to a surrogate endpoint is particularly attractive because biomarkers can be measured more quickly and easily and at lower cost than can true clinical endpoints, or when clinical endpoints are excessively invasive or when their use would be considered unethical.

## PK/PD Modeling of Biomarkers in the Early Phase of Drug Development (Colburn)

There are numerous stages along the development cycle where the development of biomarkers and PK/PD modeling can add value. Incorporation of PK/PD studies throughout preclinical and clinical development may lead to earlier identification of optimal dosing regimens in clinical development and may reduce the overall time of drug development. Beyond the traditional paradigm of using fractions of the nonclinical toxic doses in animals to design first-in-human dosing schedules, the use of PK/PD modeling in early preclinical development allows one to define more precisely the dose–concentration–pharmacological effects and dose–concentration–toxicity relationships with the use of key efficacy and safety biomarkers. The extrapolation of these results to humans using a combination of in vitro and in vivo data can be

particularly helpful in determining the appropriate dosing regimen for phase I studies and in guiding dose escalation in order to achieve the systemic exposure in humans that is expected to be associated with the desired effect on the biomarker and ultimately, the clinical outcome. Overall, the use of validated biomarkers and the application of PK/PD modeling and simulation principles represent an opportunity to identify optimal drug candidates and possibly to develop drugs in the shortest time frame possible [7–9].

PK/PD modeling output can be no better than the biomarkers or surrogate endpoints used for the modeling (i.e., the input). As we increase our understanding of biomarkers, surrogate markers, and disease and drug mechanisms, PK/PD modeling inputs and outputs will improve and, consequently, predictive power will improve.

## PK/PD Modeling of Biomarkers in Late Phases of Drug Development

The usefulness and validity of PK/PD models for the evaluation of dose–concentration–effect relationships are not limited to well-designed clinical studies with relatively small groups of patients and frequent measurements of concentration and effect. It has also been shown for observational data obtained from large clinical trials with sparse and imbalanced sampling schedules by applying population modeling techniques. Population PK/PD modeling is based primarily on the nonlinear mixed-effects regression models introduced by Sheiner and co-workers and makes possible the characterization of dose–concentration effect relationships in populations rather than individuals, thereby providing the opportunity to identify and account for sources of interindividual PK and PD variability [21,22].

In addition, the increased understanding of drug action derived from biomarker response and PK/PD-based drug development may lead to a definition of strategies for individualization of drug dosage regimens to ensure optimal therapeutic outcome in subpopulations of patients. The building of a PK/PD database during drug development can provide an essential framework for continued refinement and improvement during postmarketing drug use, allowing one to answer specific questions without the need to perform additional studies.

## Clinical Trial Simulation

Population PK/PD modeling has been used successfully for numerous drugs. These models may be descriptive and/or predictive of the time course of PD effects. When properly developed, predictive models may be used to guide starting doses and regimens (as well as adjustments of dosage and dosing regimens in special populations), add evidence to the certainty of the decision to allow market access, and provide a better understanding of outcomes from clinical studies [23,24]. Clinical trial simulations are usually motivated as follows:

- To improve the clinical trial process by maximizing the probability of trial objectives being attained with reduction of unnecessary costs
- To improve decision making in drug development by providing an objective framework for safety, efficacy, and commercial risk assessments
- To improve the overall efficiency of drug development in terms of informativeness, economy, and speed

Modeling and simulation may help predict the results of future drug trials and can be used at decision points in the drug development process to assess quantitatively the risk of moving forward with a candidate drug.

## CASE STUDIES

In recent years, PK/PD modeling has developed from an empirical descriptive discipline into a mechanistic science that can be applied at all stages of drug development. Preclinical PK/PD studies may prompt a series of important mechanistic studies to explore the relationship between plasma concentrations and the resulting effect on a biomarker in later stages of clinical drug development. The application of PK/PD modeling to preclinical pharmacology studies may help to provide information on drug effects and actions that would be difficult to obtain in human subjects. As such, preclinical and clinical PK/PD studies constitute a scientific basis for rational drug discovery and development. The following preclinical and clinical cases studies are presented to demonstrate how modeling techniques have improved the overall understanding of PK/PD relationship of biomarkers.

### Case Study 1 (Preclinical): Pharmacokinetic–Pharmacodynamic Modeling of the Respiratory Depressant Effect of Norbuprenorphine in Rats

The objective of this investigation was to characterize the PK/PD correlation of buprenorphine's active metabolite norbuprenorphine for the effect on respiration in rats [25]. Following intravenous administration, the time course of plasma concentrations of buprenorphine and norbuprenorphine were determined in conjunction with the effect on ventilation as determined using plethysmography, a test used to measure changes in air volume. The PK of norbuprenorphine was best described by a three-compartment PK model with nonlinear elimination. A saturable biophase distribution model with a power PD model described the PK/PD relationship best as presented in Figure 4.

No saturation of the effect at high concentrations was observed, indicating that norbuprenorphine acted as a full agonist with regard to respiratory depression. By simulation, it was shown that following intravenous administration of buprenorphine, the concentrations of norbuprenorphine reached values that were well below the values causing an effect on respiration. In

**Figure 4** PK/PD model for respiratory depressant effect of norbuprenorphine and norbuprenorphine. (From ref. 25, by permission of the American Society for Pharmacology and Experimental Therapeutics.)

conclusion, the PD of the metabolite norbuprenorphine was determined to be markedly different from the PD of the parent compound buprenorphine with regard to the receptor association–dissociation kinetics, the in vivo potency, and the intrinsic efficacy for the respiratory depressant effect. The values of these norbuprenorphine concentrations are well below values causing an effect on respiration. Therefore, it was concluded norbuprenorphine does not contribute to the overall respiratory depressant effect of buprenorphine. These results were consistent with the experience from clinical use of buprenorphine in patients.

## Case Study 2 (Preclinical): Pharmacokinetics and Pharmacodynamics of PEGylated IFN-β1a Following Subcutaneous Administration in Monkeys

The purpose of this study was to characterize the PK/PD properties of a new polyethylene glycol (PEG) conjugate formulation of interferon-β1a (IFN-β1a) following subcutaneous (SC) administration in monkeys [26]. Single SC injections of 0.3, 1, and 3 MIU/kg of PEG-IFN-β1a were administered to three

**Figure 5** PK/PD model for the effect of IFN-β1a on neopterin. (From ref. 26, by permission of Springer Science and Business Media.)

groups of cynomolgus monkeys. Plasma concentrations of drug and neopterin, a classic biomarker for IFN-β1a, were measured at various time points after dosing using an ELISA assay. PK/PD profiles were first described by noncompartmental methods, and then a pooled analysis was performed using an integrated mathematical model, where fixed and delayed concentration–time profiles were used as a driving function in an indirect stimulatory response model as presented in Figure 5.

The PK component of IFN-β1a was assessed using a standard linear two-compartment model with a first-order rate constant for absorption to and elimination from the central compartment of IFN-β1a. The PD model was a modified stimulatory indirect response model, with a zero-order rate constant of neopterin production ($k_{in}$), a first-order rate constant of neopterin elimination ($k_{out}$), where the driving function (i.e., concentrations of IFN-β1a) was delayed by a time-lag parameter ($\tau$). Neopterin concentrations followed a typical dose-dependent biphasic pattern. Pooled PD profiles were well described by the PK/PD model, and the neopterin elimination rate was consistent with previous estimates. The PEG modification of IFN-β1a provided enhanced drug exposure and comparable pharmacodynamics to unpegylated IFN-β1a.

### Case Study 3 (Clinical): Modeling of Brain D2 Receptor Occupancy–Plasma Concentration Relationships with a Novel Antipsychotic

PK/PD modeling using functional imaging methodology such as positron-emission tomography (PET) may be a very useful tool for early clinical development of antipsychotic compounds, especially in suggesting initial doses for further clinical studies. The purpose of this study was to assess PK/PD relationships of YKP1358 to guide decisions for further clinical study designs. YKP1358 is a novel serotonin (5-HT2A) and dopamine (D2) antagonist that

**Figure 6** PK/PD model used to assess the relationship between YKP1358 and D2 receptor occupancy. (From ref. 27, by permission of Macmillan Publishers Ltd.)

fits the general profile of an atypical antipsychotic drug [27]. A D2 receptor occupancy study was conducted in healthy volunteers using PET to measure the D2 receptor occupancy of YKP1358 and to characterize its relationship to plasma drug concentrations. A single oral dose, parallel group, dose-escalation (100, 200, and 250 mg) study was performed in 10 healthy male volunteers with the PET radiotracer [$^{11}$C]raclopride. The relationship between plasma concentration and D2 receptor occupancy was analyzed with an indirect link model that included an effect compartment, as well as an equilibrium rate constant ($k_{e0}$), as presented in Figure 6.

Results of the study demonstrated that YKP1358 possesses potential antipsychotic effects based on the D2 receptor occupancy data. Considering the D2 receptor occupancy data, effective doses in patients were predicted to be greater than 250 mg twice a day. This is the first study in which the relationship between plasma concentration and the biomarker of D2 receptor occupancy was modeled using nonlinear mixed-effects modeling. It is anticipated that these results will be useful in estimating the initial doses of YKP1358 required to achieve a therapeutically effective range of D2 receptor occupancy in subsequent studies.

## Case Study 4 (Clinical): Semimechanistic and Mechanistic Population PK/PD Model for Biomarker Response to Ibandronate

Biomarkers of bone turnover provide a rapid and accessible means of evaluating physiological responses to antiresorptive therapies. Recent evidence also suggests an association between the magnitude of biomarker suppression and the likely response in terms of bone mineral density (BMD) change and fracture risk reduction. This association suggests that these

biomarkers are on the causal pathway for prevention of fracture following administration of bisphosphonates. As such, biochemical markers of bone turnover can offer a timely indication of the likely efficacy associated with nominal dosing regimens. The aim of this project was to develop and validate a pharmacological model for ibandronate, a new bisphosphonate for the treatment of osteoporosis, capable of describing its PK in serum and urine, and the urinary excretion of the C-telopeptide of the α chain of type I collagen (uCTX), a sensitive biomarker of PD response to ibandronate [28]. A classical PK/PD model was developed that described accurately the PK of intravenously administered ibandronate and its effect on the biomarker, as presented in Figure 7.

A four-compartment PK model was used, with an indirect PD response model with a uCTX formation rate (KS) and uCTX degradation rate constants (KD). Ibandronate in the "bone compartment" was assumed to inhibit osteoclast activity and hence the rate of synthesis (KS) and the urinary excretion of CTX. The complex physiological PK/PD model adequately described the PK of intravenously administered ibandronate in serum and urine as well as the time course of uCTX. To reduce processing times, the classical PK/PD model was simplified using a *kinetics of drug action* or kinetic (K)-PD model (i.e., a dose–response model, as opposed to a dose–concentration–response model). The model was subsequently extended to consider the influence of supplemental therapy on the PD response and subjected to external validation by retrospectively simulating the time course of uCTX change reported in a phase III study and in a phase II/III study of intravenous ibandronate. In summary, a pharmacostatistical model was developed and validated that adequately described the time course of uCTX change after oral and intravenous ibandronate therapy for osteoporosis. This model is currently being used to aid in the development of novel intermittent oral and intravenous regimens for ibandronate.

**Figure 7** PK/PD model used to assess the relationship between ibandronate in serum and urine and the urinary excretion of uCTX. (From ref. 28, by permission of Wiley-Blackwell.)

## Case Study 5 (Clinical): Receptor Theory–Based Semimechanistic PD Model for the CCR5 Noncompetitive Antagonist Maraviroc

Maraviroc (UK-427 857), a selective and reversible CCR5 co-receptor antagonist, has been shown to be active in vitro against a wide range of clinical isolates [29]. In human immunodeficiency virus type 1 (HIV-1)–infected patients, maraviroc given as monotherapy for 10 days reduced HIV-1 viral load dose dependently by up to 1.6-$\log_{10}$ copies, consistent with currently available agents that comprise the cornerstone of highly active antiretroviral therapy. The objective of this study was to develop a novel combined viral dynamics/operational model of (ant-)agonism that describes the PD effects of maraviroc, a noncompetitive CCR5 inhibitor, on viral load. A common theoretical framework based on receptor theory and the operational model of (ant-)agonism has been developed to describe the binding of maraviroc to the CCR5 receptor and the subsequent decrease in viral load. The effect of maraviroc was modeled using an inhibitory $E_{max}$ model in the PD model acting on the infection rate constant of the virus and target cells. With this parameterization, it was assumed that the antagonistic effect of maraviroc is noncompetitive, which is consistent with recent in vitro findings. In terms of receptor theory and an operational model of drug action, the viral replication process was modeled as a binding–stimulus–response cascade in which the virus acts as an agonist, as shown in the five steps in Figure 8.

In the binding–stimulus–response cascade shown, $T_{max}$ is the maximum concentration of activated target cells that can be infected, $V$ is the virus con-

**Figure 8** Viral dynamics–operational model (binding–stimulus–response). (From ref. 29, by permission of Wiley-Blackwell.)

centration, $K_v$ is the theoretical concentration of viruses that elicits half the maximum binding to the activated receptors on the target cells, and $K_{ex}$ is the theoretical stimulus ($S_X$) at step $X$ that elicits half the maximum response ($S_{X+1}$) at step $X + 1$ ($X = 1$ to 5). This new model provided an explanation for the apparent discrepancy between the in vivo binding of maraviroc to the CCR5 receptor ($KD$ = 0.089 ng/mL) and the estimated in vivo inhibition ($IC_{50}$ = 8 ng/mL) of the infection rate. The estimated KE value of the operational model indicates that only 1.2% of free activated receptors are utilized to elicit 50% of the maximum infection rate. The model developed suggests that the target cells, when activated, express more receptors (spare receptors) than needed. In the presence of maraviroc, these spare receptors first require blocking before any decrease in the infection rate, and consequently in the viral load at equilibrium, can be detected. The model allowed the simultaneous simulation of the binding of maraviroc to the CCR5 receptor and the change in viral load after both short- and long-term treatment. The current model will be used to guide the selection of the optimal dosage regimen for maraviroc in HIV-1–infected patients.

## SUMMARY

Considering the complexity, risk, and cost involved in drug discovery and development processes, it is imperative that companies adopt strategies and technologies that will facilitate the identification and development of new therapies. The development of biomarkers and clinical trial endpoints as well as PK/PD modeling were recognized as key elements that can improve decision making and render development processes more effective and more likely to result in safe and beneficial products for patients.

A new framework for biomarker and surrogate endpoint use in drug development was recommended by the FDA. As part of this process, disease-specific biomarkers will be evaluated to determine whether some biomarkers may be elevated to surrogate endpoints. This will be particularly attractive because biomarkers can be measured more quickly and easily and at lower cost than can true clinical endpoints. Appropriate PK/PD modeling of biomarkers and surrogate endpoints will facilitate proof-of-concept demonstrations for target modulation; enhance the rational selection of an optimal drug dose and schedule; aid decision making, such as whether to continue or close a drug development project, accelerate drug approval, minimize uncertainty associated with predicting drug safety and efficacy, and decrease the overall costs of drug development.

The future of PK/PD modeling of biomarkers holds great challenges and great promises. Pharmaceutical companies that implement PK/PD modeling of biomarkers in their early drug development strategy should have a distinct competitive advantage, with powerful insights and guidance for effective and efficient rational drug development, and by providing safe and efficacious

medicines for individual patients. Although the science of PK/PD modeling and biomarkers is constantly evolving, these disciplines provide a continuous process to link what has been learned from today's drug development cycle to the next generation of biomarkers, assays, and mechanism-based models.

## INTRODUCTION

Biomarkers have been used for many years to predict and track biological changes in tissue and organ systems. The conceptual framework for their use was captured in the output of the Biomarkers Definitions Working Group [1], which provided a valuable working definition and some challenges to the scientific community. Here, a *biomarker* was defined as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes or pharmacological responses to a therapeutic intervention" [1]. The working group noted that biomarkers may have the greatest value in early efficacy studies and safety evaluations with applications that could include prediction and monitoring of clinical response to an intervention [1].

### Biomarkers in Drug Development

Biomarkers have been used for many years as indicators of biological change. In the course of drug development, biomarkers enjoy utility both as predictors

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

**Figure 1** Biomarkers in clinical medicine. Biomarkers of safety and efficacy can be used together as part of the overall data set to assist in decision making.

of possible efficacy and also as warning signs of potential toxicity (Figure 1). For efficacy endpoints, biomarkers are used to address the pharmacodynamic question "What is the drug doing to the patient?" commensurate with desired outcomes such as receptor modification or blood glucose changes. For safety endpoints, biomarkers may be used as indicators of unwanted endpoints such as tissue damage or adverse hematology.

Although these two types of biomarker serve diverse purposes, the parameters dictating their identification, development, and utility are very similar. However, there is one key aspect in which safety biomarkers differ; safety biomarkers are most useful when they predict rather than report damage. For example, an efficacy biomarker can provide rapid confirmation that the drug has hit its target, perhaps by confirmation of growth factor receptor inhibition in a skin biopsy. However, a safety biomarker of liver damage would ideally precede the damage (either in dose or time) to be of maximum use to the clinician. Despite this, biomarkers that report rather than predict can still be useful if they prevent further damage or permit cessation of treatment and subsequent recovery.

## Toxicity Biomarkers In Vitro

The driving force for better clinical biomarkers of potential adverse events is to monitor patient safety, and many such biomarkers will be discovered and developed within the context of human medicine. However, from a nonclinical

perspective the discovery and development of toxicological biomarkers facilitates the translation to the clinic of knowledge that will avoid or minimize the risk of occurrence of a potential unwanted outcome identified in animal studies. Thus, it is key to identify preclinical biomarkers of the adverse response of animals to potential new drugs and to evaluate fully their relevance and applicability to humans.

Potential biomarkers can be identified in vitro, and their translation to in vivo, either in animal or humans, evaluated at a later date. This concept is developed later in this review with specific examples and case histories. One argument against this approach is that findings in animals in vivo or in animal-derived tissue in vitro may not be relevant for human safety; however, the job of the clinician is to manage the best possible therapy while minimizing the risk of adverse reactions. Thus, such data would form part of an integrated assessment of safety and efficacy that can inform preclinical and clinical decisions.

Clinically useful biomarkers of toxicity can be derived from appropriately designed preclinical experiments, and such biomarkers can significantly assist safe progression into the clinic with an approach design to minimize patient risk. These biomarkers can be derived from in vitro or in vivo mode-of-action studies in preclinical species then translated to potential clinical use or, as we present here, could already be established in clinical practice. This translational science approach requires close collaboration between the clinical and the preclinical scientists.

## Characteristics of Biomarkers

An important consideration in the use of biomarkers is the practicality of subsequent analysis, which is likely to be far more successful and robust if based on an uncomplicated physiological or biochemical assay that can be carried out with minimal training and preexisting equipment (Figure 2). Nonetheless, the need for specialist techniques or expertise should not exclude a potential biomarker, especially where it contributes to advancing therapies for a serious or unmet medical need. Other practical considerations include the need for assays to be transferrable across international boundaries, supported by low background and variability of the measured parameter coupled with a robust increase or decrease signifying the biological endpoint of interest. Indeed, lower and upper limits for normal values would be better if minimally influenced by age, gender, or race within the human population. Similarly, a biomarker of drug-induced toxicity would be better if it were largely unaffected by disease states expected in the patient population of interest or, indeed, any co-medication that might be present or recently administered. However, this is often not the case, and the best that can be expected is some understanding of these relationships to mitigate against difficult or erroneous interpretation. In addition, an ideal biomarker should exhibit

**Figure 2** Technical aspects of biomarker utility. Biomarkers must be sufficiently robust biologically and technically to transfer across patient groups and across international boundaries. This is illustrated by the different variables that need to be overcome or accommodated in the assay.

sufficient sensitivity (not too many false negatives) and specificity (not too many false positives) to underpin clinical decisions.

As well as the technical aspects of biomarker assays, there are additional practical considerations to enhance appropriateness and usability. First, a biomarker needs to be accessible and ideally could be noninvasive. If this is not possible, a biomarker could be measurable in blood and other body fluids obtained with minimal additional impact on the subject. If this cannot be achieved, biomarkers may be detectable with increasing impact on the patient via a peripheral or central biopsy. Finally, biomarker research for the advancement of medical knowledge can be conducted after autopsy. Examples of noninvasive methods would include standard physiological measures of cardiovascular parameters such as blood pressure, heart rate, and electrocardiogram, or could be ophthalmological. Fluids could include feces, saliva, and urine, in addition to standard blood sampling. Skin and hair follicles would be examples of peripheral biopsy and muscle and liver needle samples provide the most common route of more invasive biopsy.

## Biomarkers of Safety

One key aspect where biomarkers of safety differ from those of efficacy is that they preferably predict rather than report the biological effect they are flagging. Thus the biomarker should ideally precede that biological effect either in dose (i.e., be detectable at doses below where the damage occurs) or in time

(be detectable perhaps after one dose when the damage requires repeated dosing). These biomarker characteristics would provide support and confidence to the clinician during dose escalation in early clinical trials or during the transition from single to multiple doses. During later clinical development, a predictive biomarker could monitor for onset in a patient who is beginning to develop toxicity perhaps after several months of drug use. In the absence of evidence that a biomarker can predict onset, an ideal biomarker of drug-induced toxicity would characteristically show detectable changes prior to any serious or irreversible tissue injury and would also show reversibility of the biomarker signal upon removal of the toxicological insult.

## IN VITRO TOXICITY BIOMARKERS

Having considered some general points on the development and validation of toxicity biomarkers, we now present several working examples that explore the concept of in vitro toxicity biomarkers and their translation to the clinic. Opportunities and caveats are explored with an emphasis on assisting clinical progression and decision making. Toxicity biomarkers in the in vitro context are defined as quantitative measurable characteristics that serve as indicators of a pathologic process or related biochemical or molecular events.

### Endocrine and Exocrine Pancreatic Toxicity

The potential for development of clinical drug-induced diabetes is well recognized, and molecules such as cyproheptadine and structurally related compounds such as cyclizine and chlorcyclizine have been shown to cause pancreatic islet toxicity. However, this is not unique to this class of structurally related compounds because a similar finding has been observed following oral administration of some quinolone antimicrobial agents. In vivo, this effect is characterized by cytoplasmic islet vacuolation, decreased insulin secretory granules, decreased circulating insulin levels, intolerance to glucose challenge, and increased glycosylated albumin. The working hypothesis is that these compounds were associated with functional impairment of insulin synthesis and/or secretion, and an in vitro screen would be invaluable in identifying this liability early in the drug development process.

The clonal insulin-producing cell line RINm5F is widely used as a model to detect compound-induced loss and/or reduction of insulin in vitro that is comparable to in vivo findings. Using this in vitro model, it was determined that cyproheptadine and selected analogs caused inhibition of insulin biosynthesis without any effects on pre-pro-insulin mRNA. These data suggested that inhibition of transcriptional regulation of insulin was an unlikely mode of action responsible for cyproheptadine-induced pancreatic islet cell toxicity. The limitation of the RINm5F cells is that they are not glucose-sensitive and as such, cannot be used to study glucose-dependent insulin secretion. When

this effect is suspected, the use of Min 6 (mouse) and HT15 (hamster) cells are recommended.

Isolated mouse pancreatic acini provide an ex vivo tool used to assess potential exocrine pancreatic toxicity. This is achieved by evaluating digestive enzyme secretion through an assessment of basal amylase and amylase release in response to carbachol and cholecystokinin octapeptide (CCK8). In vitro, cyproheptadine at high doses causes marked release of amylase without any breaks in structural integrity, thus ruling out cytotoxicity as the likely cause of the marked amylase release. Furthermore, cyproheptadine can abolish carbachol-stimulated amylase release, and this may be related to its anti-muscarinic pharmacological property. This approach can serve as an in vitro toxicity screen to eliminate and/or reduce undesirable effects on the exocrine as well as endocrine pancreas and, additionally, the pathophysiology of these potential effects can be investigated.

## Bone Marrow Toxicity

Within the last decade, clinical hematopoietic toxicity has accounted for 10 to 20% of approved drug withdrawals and is a major cause of early candidate drug attrition. Identification of potential hematopoietic toxicity as a hazard is done only when in vivo studies are initiated even though there is strong evidence suggesting that in vitro assays could have a very good predictability. A three-tiered approach that enables a large number of compounds to be evaluated at the lead optimization phase was developed to improve the assessment of potential hematotoxicity. A key question in this approach is whether there is clinical translation and predictability of this combined in vitro, in vivo preclinical evaluation.

This novel approach uses multiple assays, cell lines representative of broad bone marrow lineages (myeloid, erythroid, lymphoid, and stromal), and a nonhematopoietic cell line (tier 1). In general, there is a good correlation between the mouse myeloid cell line and the mouse colony-forming unit/GM (CFU-GM) assays and compounds with lineage-specific in vivo bone marrow toxicity showed similar lineage specificity in the tier 1 assays. An erythrotoxicant such as chloramphenicol has an $IC_{50}$ value of 8 μM in the erythroid cell line assay and >100 μM for the other cell lines. CFU assays (tier 2) are then run to qualify and confirm the findings of tier 1. Tier 2 consists of mouse, rat, dog, and human CFU-GM assays to predict species sensitivity, but these assays are tedious and time consuming, enabling only a limited number of compounds to be evaluated. Increased throughput was achieved when a 96-well plate CFU-GM assay was developed that yielded results that correlated well with the traditional CFU-GM assay. The data generated from the tiers 1 and 2 can trigger frontloading of in vivo studies to evaluate a more comprehensive hematology profile and include use of additional technologies such as flow cytometry (tier 3). In summary, a three-tiered approach using in vitro, ex vivo, and in vivo studies allows rapid, high-throughput assessment of compounds

with potential chemistry-related bone marrow toxicity to be eliminated in the early preclinical stages of drug development.

## Liver Toxicity

The overall goal of developing an in vitro toxicity testing system is for inclusion in a toolbox as an element of investigative toxicology. This should contribute to hypothesis-based research aimed at identification of mode-of-action-based toxicity biomarkers, which can extend to preclinical and clinical phases of drug development. The current preclinical and clinical diagnostic panel used to monitor hepatocellular toxicity has been quite reliable except in cases of human drug-induced liver injury, which occurs with a low incidence and prevalence, ranging from 1 in 10,000 to 1 in 100,000. This is also referred to as *idiosyncratic hepatotoxicity*, meaning that the adverse events are a consequence of individual and unpredictable patient responses. It is well recognized that there is an urgent need to identify and develop a more successful prediction model coupled with diagnostic and prognostic biomarkers for drug-induced idiosyncratic liver injury in humans. This type of human liver toxicity is multifactorial, including individual-specific responses, and because of this, it is highly unlikely that any preclinical and/or clinical studies can be powered appropriately to unmask this risk. Furthermore, it is difficult to assess the value of our preclinical toxicology studies and their relevance to predicting drug-induced idiosyncratic liver injury in humans, because we lack understanding of the mode of action and pathophysiology of this unique type of toxicity. However, there is extensive literature related to the predictability of hepatotoxicity, and there is good concordance with in vitro and in vivo assessments.

Several different strategies have been employed to detect various forms of hepatotoxicity, including, necrosis, apoptosis, and phospholipidosis. The in vitro hepatotoxicity predictive strategy uses hepatic microsomes; immortalized cell lines; primary hepatocyte cell cultures from humans, rodents, and nonrodents; and liver slices. The latter, in particular, enables a better approximation and evaluation of metabolites that may be formed and an assessment of their hepatotoxicity potential determined and in vitro–in vivo comparisons made. For example, using this approach, studies were done to characterize the metabolic profile of troglitazone, an approved drug that has now been withdrawn from the market because of hepatotoxicity and hepatic failure requiring liver transplants. Data from a series of studies using rat and human hepatic microsomes as well as in vivo rat studies suggested that troglitazone hepatotoxicity was caused by several reactive intermediates covalently binding to hepatic proteins that may undergo redox cycling and induce oxidative stress, causing cell damage. This hypothesis was strongly supported by the data suggesting that not only is troglitazone an inducer of P450 3A, but is also responsible for metabolism of the thiazolidinedione ring, a key structural element of many of the peroxisome prolifercator–activated receptor (PPAR) agonists.

Taken together, troglitazone acts as an inducer of enzymes that catalyzes its biotransformation to chemically reactive intermediates; this autoinduction of its own metabolism is ultimately detrimental to the cells. Additionally, this combined approach was able to show that in humans these intermediates could be formed, thus identifying a potential etiology for troglitazone-induced hepatotoxicity in humans. Utilization of liver slice technology, co-cultures, and whole liver perfusion can be quite useful, but these are low-throughput assays that are not always suitable for screening. The advantage is that toxicity to the biliary and other hepatic cellular constituents can be assessed. Thus predicting the hepatotoxicity potential using in vitro cell culture systems can also employ the well-recognized preclinical and clinical biomarkers of hepatocellular damage, such as ALT (alanine aminotransferase), AST (aspartate aminotransferase), GLDH (glutamate dehydrogenase), MDH (malate dehydrogenase), PNP (purine nucleoside phosphorylase), and PON-1 (paraoxonase-1). Other enzymes, such as ALP (alkaline phosphatase), GGT (γ-glutamyl transferase) and 5′-nucleotidase (5′NT) can also be used when toxicity to the biliary tree is suspected.

Cytotoxicity (necrosis and apoptosis) in vitro is the primary endpoint, and as such, biomarkers for potential hepatotoxicity clinical monitoring should include necrosis as well as apoptosis. Recent evidence suggests that this may be possible by measuring the soluble pool of cytokeratin 18 (CK18) and the caspase-cleaved CK18 fragments in conjunction with the traditional markers. The in vitro surrogate system can also provide valuable information on the suitability of the appropriate biomarker and potential mechanism of action related to toxicity, such as mitochondrial dysfunction, metabolic pathways, and/or CYP450 induction.

In summary, in vitro hepatocyte cell culture systems and tissues derived from in vivo studies will identify the appropriate biomarker for monitoring preclinical and clinical hepatotoxicity but these data can also contribute to hypothesis-driven mode-of-action investigative toxicity studies. This will include molecular profiling, metabonomics, transcriptomics, and proteomics, all of which are useful tools that could aid in identification of novel biomarkers of hepatotoxicity.

## Phospholipidosis

Phospholipidosis (PLD) is characterized by concentric-layered multilamellar intracellular lysosomal inclusion bodies that are often composed of complex phospholipids, parent drug, and/or metabolites. Accumulation will often occur in several different cell types of the hepatobiliary, immune, and nervous systems. Typically, hepatocytes, biliary epithelial cells and macrophages of lymph nodes, and pulmonary alveoli and ganglia and nonganglia neuronal cell bodies of the central nervous system can be affected. The evidence to date suggests that phospholipidosis is a structural-related toxicity of cationic amphiphilic compounds irrespective of pharmacologic action. The finding of phos-

pholipidosis may also be associated with inflammation, severe organ damage, and possibly impairment of immune function. Although drugs are marketed that cause phospholipidosis preclinically and clinically, this is an undesirable profile for potentially new candidate drugs, and as such, this liability should be identified and avoided early in the drug discovery process. Therefore, high-throughput in vitro predictive screens can add value, particularly if phospholipidosis potency can be ranked and supported by in vivo data.

Several methodologies have been evaluated to assess neutral and phospholipid content as an index of phospholipidosis in cells growing in culture. However, accumulation of NBD-PE as a result of cytotoxicity induces false-positive results, particularly at high concentrations. Recently, a high-throughput, validated, predictive, sensitive, and selective multichannel fluorescence-based in vitro PLD assay was developed to reduce the false-positive limitation of cytotoxicity. This assay uses I-13.35 adherent mouse spleen macrophages cultured in 96-well plates with fluorescent-tagged phospholipids. Cells with an intact nucleus were differentiated from dead cells using ethidium staining and cell gating that rejects dead cells. Using this improved technique, 26 of 28 positive phospholipidogenic compounds were identified. These findings aided application of this methodology to other techniques, such as flow cytometry, which may be used in preclinical toxicology studies and clinical trials. For example, flow cytometric analysis coupled with Nile Red staining was used to detect neutral and phospholipids in a monocyte cell line, U397. Application of this methodology was utilized in (in vivo) toxicology studies, and this raised the possibility that preclinical toxicology and clinical assessment of phospholipidosis could be done using peripheral blood cells and flow cytometry.

## CONCLUSIONS

Overall, there is a compelling need for in vitro toxicity biomarkers for clinical endpoints. Toxicity biomarkers in the in vitro context are defined as quantitative measurable characteristics that serve as indicators of a pathologic process or related biochemical or molecular events. Conceptually, bridging biomarkers of toxicity should include not only the traditional parameters of biofluid and physiological measurements, but also measurable endpoints that could serve as indicators of potential adverse events preclinically and clinically even though they have been derived from in vitro, ex vivo, and in vivo studies. The use and application of this combination will undoubtedly improve the toxicologist's ability to identify human hazards so that the appropriate risk assessment and management strategy can be developed. In developing in vitro assays to identify biomarkers with potential clinical application and utility, a clear understanding and determination of what that biomarker will assess must be defined. For example, exaggerated pharmacologic action of a molecular target may be associated with an undesirable effect resulting in toxicity. In

such cases, single/multiple markers and/or assays may be required for utilization in screens during the early drug discovery phase, with continued assessment in preclinical and clinical development. If successful, these data can be invaluable in deriving the therapeutic index of a drug. In the case of a specific target organ toxicity, the ultimate goal is to identify biomarkers of toxicity that can be used as a general screen that reflects cellular damage, regardless of mode of action in a high-throughput manner. Therefore, it is imperative that in vitro assays and the appropriate platforms be developed to identify relevant toxicity biomarkers that will be useful during preclinical and clinical development.

## INTRODUCTION

The cost of developing new drugs continues to rise and demands an ever-increasing percentage of total research and development (R&D) expenditures [1]. Recent studies have shown that there is less than a 10% success rate between the first human trials and the launch of a new product [1]. When coupled with an attrition rate of over 70% in phase II and nearly a third of all new compounds in phase III trials [1–3], the gravity of the need for reliable, early-decision-making capability is evident. All pharmaceutical companies are focused on ways to reduce the cost of discovering and developing new drugs. In general, three areas have received the greatest attention: (1) improving target validation, (2) selecting candidates with a greater chance of success, or (3) identifying those compounds that will fail earlier in their development. Inadequate efficacy or poor safety margins are the two main reasons for compound attrition. Therefore, developing a strategy for development of safety

and efficacy biomarkers is key to early prediction of compound success or failure. Utilization of biomarkers in preclinical testing and ex vivo human testing may provide valuable information for compound progression and success in the clinic, but it is not without problems.

Studying the effects of markers on disease processes is not new. It has probably existed for centuries, as evidenced by such obsolete practices as tasting urine to determine the diabetic status of a patient. Utilization of biomarkers for disease diagnosis and prognosis has escalated dramatically during this century with the improved diagnostic power, reliability, and speed of routine clinical pathology, biochemical, and genomic data. However, when studying the specific effects of a drug on marker activity, utilization of biomarkers has a more recent history. One of the earliest documented cases may be the early trials of lamotrigine, which effectively utilized the electroencephalograph (EEG) as a biomarker and demonstrated decreased epileptiform activity [4]. Twenty years after the lamotrigine study the urgency for relevant and early biomarkers of safety and efficacy during drug development has been recognized, and it is not uncommon that each new drug development program is accompanied by a biomarker request.

Not only has the frequency of biomarker development exploded, but the timing of biomarker utilization has been pushed earlier in development. There is an ever-increasing demand to test and screen potential candidates before good laboratory practices (GLP) studies and commitment to human trials. Two problems inherently complicate the use of early biomarkers to preclinical outcomes: (1) truly understanding the disease process and the therapeutic intervention process, and (2) species–species differences that may alter the translation and application of the biomarker.

Understanding the disease process appears obvious, but as already noted, understanding the target is still a key area for decreasing attrition. Regardless of the expanding body of knowledge surrounding disease processes, infectious diseases may be the lone area where the disease process is fully understood. Successful therapeutic intervention and drug sensitivity can be predicted accurately with well-characterized biomarkers of causal organism growth and survival [5]. For biomarkers to be truly effective in drug development, they need to reflect a highly specific biochemical or molecular change that occurs in the disease process, is altered by the therapeutic intervention, and occurs prior to any downstream effects on clinical endpoints. This is a lofty goal, as most disease processes affect multiple pathways, and feedback mechanisms further complicate the overall biology. The further impact of nontranslatable, species-specific characteristics makes daunting the task of providing biomarkers early in development. There are, however, diseases and biological pathways that have a fairly broad acceptance regarding the essential components. Additionally, certain areas of drug development target activation or inhibition of a highly specific molecule or receptor within those pathways. These conditions provide a unique opportunity for biomarker success when conducted early in the drug discovery process.

The coagulation pathway is an example of a well-characterized model, and specific inhibitors of this pathway are being explored actively as new candidates for anticoagulant therapy. One of the documented areas is the utilization and challenge of early implementation of biomarkers to predict the clinical outcomes of factor Xa (FXa) inhibitor compounds. Venous and arterial thromboembolic disorders have a substantial impact on human health and morbidity [6]. Although these conditions have been treated for many years with the vitamin K antagonist warfarin (coumadin), or with intravenous or subcutaneous heparin administration, the opportunity to provide therapeutic intervention with a safer profile, fewer side effects, less intra- and intersubject variability, a better route of administration, and less need for continuous coagulation monitoring is attractive. Novel coagulation therapeutics have generated tremendous interest due to the medical need and opportunity to improve on current treatment strategies. FXa occupies a pivotal position within the coagulation cascade and is a highly attractive candidate as a target for novel coagulation intervention. This enzyme links the intrinsic and extrinsic coagulation pathways and is the rate-limiting step in thrombin formation [7].

Changes within the intrinsic coagulation pathway are routinely monitored by a clotting assay called the *activated partial thromboplastin time* (aPTT), whereas changes in the extrinsic pathway are assessed by increases or decreases in another clotting assay called the *prothrombin time* (PT) (7, Figure 1). Both assays are assessed spectrophotometrically or mechanically and are expressed

**Figure 1** Intrinsic and extrinsic coagulation pathways.

as the time to clot formation after addition of an exogenous clot-activating agent. The aPTT is used routinely to monitor the safety and level of anticoagulation of heparin therapy and coumadin in monitored via the PT assay. Safety profiles for these compounds have been established following years of use so that fold increases over the predose aPTT or PT can be used to predict therapeutically effective doses of these drugs versus levels associated with inadequate or excessive coagulation. Additionally, aPTT and PT are routine and highly standardized clinical assays. Testing reagents are standardized and instrumentation has undergone rigorous scrutiny to pass U.S. Food and Drug Administration (FDA) requirements because of its routine use in clinical diagnostics. The reliability of aPTT and PT as biomarkers of anticoagulant therapy safety is also fairly well established. Since activation of factor X is required for completion of both the intrinsic and extrinsic pathways, it appears logical that inhibition of factor X activation should prolong both PT and aPTT.

It would be anticipated that early assessment of novel anticoagulants such as FXa inhibitors could readily be assessed with the aPTT and PT assays. Furthermore, if the new compound does not require metabolic activation, ex vivo incubation of human plasma with the compound of interest followed by aPTT and PT assessment may provide a reliable method to rapidly assess efficacy. Despite their reliability and acceptability, PT and aPTT do not always reflect the anticoagulant activity of novel compounds. Rivaroxaban is an oral direct inhibitor of activated factor X [8]. In a rat venous model of the inferior vena cava, Rivaroxaban produced dose-dependent inhibition of FXa and an increase in PT [7]. An inhibition of 32% was associated with a 1.8-fold increase in PT, and nearly 100% inhibition produced a 3.2-fold increase in PT. However, in a rabbit model 92% inhibition of FX was associated with only a modest 1.2-fold increase in PT, demonstrating that species-specific sensitivity is one of the problems associated with monitoring the newer anticoagulants with standard coagulation parameters [8]. Even Coumadin provides a good example of species-specific effects that allow a useful therapeutic for humans but a lethal pest control for rodents [9]. Despite this challenge, utilization of coagulation testing for in vivo and ex vivo screening is well documented in the development of FXa inhibitors [8,10–12].

Rarely is a single biomarker considered definitive for evaluation of safety or efficacy. The drug development approach for Otamixabin and DU-176b incorporated a series of clotting parameter assays and assays to measure the effects on thrombus formation [10–12]. Although clotting parameters would be the preferred biomarker based on the ability to monitor in plasma, use of fairly simple but reproducible assays, cost, and the ability to monitor a clinical population easily, evidence is not established that clotting assays and thrombus formation assays are interchangeable.

For Otamixaban, in vitro coagulation parameters were assessed for their ability to produce a doubling of PT and aPTT. This testing allowed a rank ordering of anticoagulant effects per species of rabbit > human > monkey >

rat > dog [10]. Additionally, aPTT appeared to be the more sensitive biomarker in all species, with aPTT doubling occurring at drug concentrations that were less than half the concentration required for PT doubling. Multiple pharmacological models of thrombosis in rats, dogs, and pigs were also conducted with Otamixaban. In rats, thrombus mass was markedly reduced by nearly 95%, with a corresponding increase in aPTT of 2.5-fold and in PT of 1.6-fold [10]. In contrast, intravenous administration of 1, 5, or 15 μg/mL Otamixaban in the pig model effectively eliminated coronary flow reserves related to this stenosis model at the middle and high dose. PT was also prolonged at the middle and high dose, but aPTT was prolonged only at the high dose. Although pigs were not listed as assessed in the species-specificity model, it suggests that the clotting parameter of choice may vary per species and may not correlate well with thromobosis assays. Furthermore, clinical trial outcomes showed that at anticipated antithrombotic and therapeutic concentrations of 100 ng/mL Otamixaban, neither PT nor aPTT changed appreciably. In contrast, alternative clotting parameters such as the HepTest clotting time and the Russell viper venom clotting time, showed substantial prolongation, again suggesting that alternatives to standard PT and aPTT may be preferable [10].

Further work with the oral FXa inhibitor DU-176b provides additional evidence that selection of the right biomarker and appropriate correlation to functional assays is critical. This study was conducted in 12 healthy male volunteers [12]. The antithrombotic effect of DU-176b was assessed by measuring the difference in size of acutely formed, platelet-rich thrombus, pre- and post-drug administration using a Badimon perfusion chamber model under low and high shear force. Subjects received a single 60-mg dose of DU-176b, and pharmacokinetic and pharmacodynamic assessments were conducted at 1.5, 5, and 12 hours postdosing. Pharmacokinetic assessments included PT, international normalization ratio (INR), aPTT, thrombin generation, and anti-factor Xa activity. Drug levels were also assessed. Badimon chamber results demonstrated a strong antithrombotic effect at 1.5 hours with a progressive return toward baseline by 12 hours. All of the pharmacokinetic endpoints showed significant change from pretreatment, suggesting that any of the parameters might be an effective biomarker of DU-176b safety and/or efficacy. However, a close statistical look at this data raises some questions. A comparison of drug concentration level to anti-factor Xa activity and clotting parameters showed the strongest correlation with anti-factor Xa activity ($r^2$ = 0.85), similar correlation with PT and INR ($r^2$ = 0.795 and 0.78, respectively), but a fairly weak correlation with aPTT ($r^2$ = 0.40). This suggests that although Otamixaban and DU-176b are both FXa inhibitors, arbitrary selection of PT or aPTT as a better predictor of drug concentration is problematic. Furthermore, when the antithrombotic effects of DU-176 assessed by Badimon chamber were compared to those obtained by clotting parameters, the correlation was even more challenging. Prothrombin time showed a correlation of $r^2$ = 0.51 at both high and low stress and the correlation with aPTT was only $r^2$ = 0.39 and 0.24 [12]. This suggests that although aPTT is used for monitoring of heparin therapy and PT

is utilized for clinical safety of coumadin, their routine use as factor Xa inhibitors by themselves is insufficient.

## CASE STUDY DATA WITH A DEVELOPMENTAL FXa INHIBITOR

Beyond the published literature that is available, data and personal observations collected during the development of another FXa inhibitor at Pfizer Global Research & Development are now provided to complete this case study approach to biomarker utilization during anticoagulant development. Development of this particular FXa inhibitor ultimately was discontinued, as this compound required intravenous administration and as such lacked marketability compared to oral FXa inhibitors. However, the lessons learned provide further documentation of species-specific and interpretational complications that arise with the utilization of accepted coagulation biomarkers to monitor anticoagulant efficacy and safety for FXa inhibitors.

### Dose Selection for Ex Vivo Experiments

In designing ex vivo experiments to evaluate potential biomarkers, selection of the appropriate drug concentration is critical. Furthermore, when experiments are conducted in multiple species, selection of the same drug concentration for all species is typically not ideal, due to species-specific drug sensitivity. Factor X concentrations vary by species, and the level of FXa inhibition is also variable. Therefore, the concentrations of FXa inhibitor utilized in this particular ex vivo evaluation were selected to achieve a range of FXa inhibition that was modest to nearly complete in all species examined. Pharmacology studies predicted that this FXa inhibitor would result in species-specific factor Xa sensitivity in the order human > dog > rat. Interestingly, this species specificity was not identical to that observed with Otamixaban [10], demonstrating that extrapolating biomarker data even between compounds in the same class may be misleading. For this developmental FXa inhibitor, human plasma was spiked to obtain final drug concentrations of 0, 0.2, 0.6, 1.2, and 6.0 μg/mL. Drug concentrations of 0, 0.4, 2.0, 8.0, and 15.0 μg/mL were selected for dog assessments and 0, 1.0, 4.0, 12.0, and 24.0 μg/mL were used for ex vivo assessments in rats to achieve a comparable range of FXa inhibition compared to that observed in human samples.

Thromboplastin is the reagent that induces clot formation in the PT assay. There is ample documentation that the type and sensitivity of thromboplastin is a critical factor in the effective and safe monitoring of coumadin administration [13–17]. To minimize this variability in PT assays a calibration system was adopted by the World Health Organization (WHO) in 1982. This system converts the PT ratio observed with any thromboplastin into an international normalized ratio (INR). This value was calculated as follows: INR = observed PT ratio$^c$, where the PT ratio is subject PT/control PT and $^c$ is the power value

representing the International Sensitivity Index (ISI) of the particular thromboplastin [18]. This system has proven to be an effective means of monitoring human oral anticoagulant therapy with coumadin and has been implemented almost universally. It allows individuals to be monitored at multiple clinics using varying reagents and instrumentation, while still achieving an accurate assessment of true anticoagulation. However, there is little or no information regarding selection of thromboplastin reagents or use of the INR for monitoring of FXa inhibitors.

Typically, the higher the ISI value, the less sensitive the reagent, and the longer the PT time produced. The most commonly used thromboplastin reagents for PT evaluation are either rabbit brain thromboplastin (of variable ISI values, depending on manufacturer and product) or human recombinant thromboplastin, typically with an ISI of approximately 1.0. Use of the INR is accepted as a more relevant biomarker of anticoagulant efficacy than are absolute increases in PT alone, at least for coumadin therapy [13]. To more fully evaluate the effect of this FXa inhibitor on INR, PT was evaluated using rabbit brain thromboplastin, with ISI values of 1.24, 1.55, and 2.21 and a human recombinant thromboplastin (0.98 ISI). Although either human recombinant thromboplastin or rabbit thromboplastin are considered acceptable reagents for the conduct of PT testing, it was unclear whether these reagents would produce similar results in the presence of an FXa inhibitor or whether the sensitivity of the thromboplastin itself would affect results.

### Effect on Absolute Prothrombin Time

Prothrombin time data obtained using rabbit brain thromboplastin with the three increasing ISI values during these ex vivo studies are presented in Table 1. The source and sensitivity of thromboplastin used in the assay affected the absolute PT value in all species, clearly demonstrating the need to standardize this reagent in preclinical assessment and to be cognizant of this impact in clinical trials or postmarketing, when reagents are less likely to be standardized. As anticipated, addition of the FXa inhibitor to plasma under ex vivo conditions increased the PT in a dose-dependent manner. This increase in PT time length was observed regardless of the ISI value (sensitivity) of the thromboplastin used and occurred in all species (Table 1). Although the absolute time for clot formation generally increased with increasing ISI, this was not true for all assessments.

Table 2 summarizes the maximum change in PT and the range of variability when rabbit brain thromboplastin of varying ISI values was compared to human recombinant thromboplastin. Again, in general, the higher the PT value, the larger the deviation between reagent types. For example, although there was a 2.1-second difference between human and rabbit thromboplastin in untreated human plasma, the difference increased from 5.5, 9.2, 12.0, 13.6, and 38.2 seconds in samples containing 0.2, 0.6, 1.2, 1.8, or 6.0 μg/mL FXa inhibitor, respectively. Dogs were much less sensitive to the type of thrombo-

plastin used and showed smaller maximum changes in PT values. In contrast, rat PT values were highly dependent on the source of thromboplastin, and samples tested with rabbit brain thromboplastin were markedly longer than with human recombinant thromboplastin. Rats showed this high level of thromboplastin dependence even in untreated control samples. Variability of PT in FXa inhibitor-treated human and dog plasma was similar to that observed in controls and did not change appreciably with increasing concentration of drug (Table 2). FXa inhibitor-treated rat plasma showed an approximately twofold increase in variability compared to control.

## Effect on PT/Control Ratio and INR

Generating a PT/control ratio by dividing the number of absolute seconds in the treated sample by the number in the control (untreated) sample provides a second method of assessing PT. If the ISI of the thromboplastin used is close to 1.0, the INR should be similar to the PT/control ratio (Table 3). The PT/

control ratio could be used effectively to normalize thromboplastin differences in untreated human, dog, or rat samples. At predicted efficacious concentrations of FXa inhibitor, the PT/control ratio effectively normalized reagent differences. However, at high concentrations of FXa inhibitor, particularly in the rat, this method lacked the ability to normalize results effectively.

Table 4 shows the corresponding INR values obtained in human, dog, and rat plasma when assessed with rabbit brain thromboplastins of increasing ISI. As anticipated, the PT/control ratio and INR were similar when the ISI was approximately 1. In contrast to the modest differences in PT when expressed as either absolute seconds or as a ratio compared to control value, the INR showed dramatic increases (Table 3). The magnitude of the INR value rose consistently with increasing ISI value and was marked. At the highest dose tested, the INR ranged from 11.1 with the 0.98 ISI reagent to 121.9 with the 2.21 ISI reagent in human samples, 5.6 to 43.4 in dogs, and 4.6 to 48.1 in rats. Assessment of PT in human, dog, or rat plasma containing this developmental FXa inhibitor was affected by the ISI of the thromboplastin selected for the

assay. However, it was not affected to the same degree as was coumadin. Consequently, using the correction calculation designed for coumadin fluctuations to obtain an INR with CI-1031 grossly exaggerated the INR value. Although INR has been used clinically to monitor anticoagulant status during coumadin therapy, it probably should not be used with FXa inhibitor administration. Coumadin therapy typically produces INR values of 2, 4, and 6 as therapeutic, above therapeutic, and critical levels, respectively. INR values of 10 to 15 may be observed in acute coumadin poisoning, but INR values higher than 15 rarely occur [19]. Clearly, the magnitude of the INR obtained in this experiment (>120 in humans), combined with the incremental increase that occurred with increasing ISI value, shows that INR values in these FXa inhibitor-treated samples were an artifact of the calculation and not associated with the true anticoagulant effects of the FXa inhibitor itself. This suggests that when INR is used in clinical trials, it is important to select a thromboplastin with an ISI value close to 1.0. In this manner, the INR will

closely approximate the PT/control ratio and give a true estimate of the anticoagulated state.

Table 5 indicates the maximum change in PT/control ratio and INR using thromboplastins with increasing ISI values (1.24 to 2.21). Changes in the PT/control ratio were modest at drug concentrations that produced increases of fourfold or less, the maximum targeted therapeutic PT value for clinical trials. The mean PT/control ratio in human samples increased maximally from 2.7 to 3.1 at twice the therapeutic dose (0.6 μg/mL). Absolute PT and PT ratios compared to baseline values were only modestly different using thromboplastin from various manufacturers, sources (human recombinant versus rabbit), and ISI. This finding indicates that absolute PT or PT/control ratio were more effective biomarkers of FXa inhibitor concentration than was INR.

## PURSUING BIOMARKERS BEYOND PT, INR, AND aPTT

Values obtained with aPTT under ex vivo conditions were less sensitive than PT to FXa inhibitor-induced elevations and often underestimated drug concentration (data not shown). Beyond PT, INR, and aPTT, the most commonly used assay to evaluate FXa inhibitors is probably the anti-factor Xa assay (anti-FXa). It seems logical that a parameter named anti-Factor Xa assay should be the ideal biomarker for a FXa inhibitor. Additionally, this assay is used routinely in clinical settings to monitor the safety of heparin, a substance that also inhibits FXa production [20]. However, this assay is little more than a surrogate marker for drug concentration. A standard curve is prepared using the administered heparin (or other FXa inhibitor), and the chromagenic assay allows determination of the drug concentration in the plasma samples via production of FXa [21]. For heparin, the anti-FXa assay appears relevant. Years of use has allowed the development of a strong correlation between the number of international units of heparin determined via the assay and clinical safety. Reference ranges have been defined for the assay and provide a rapid

estimation of under, over, or therapeutic levels of heparin administration [22]. Still variability in the anti-FXa assay has been reported and is attributable to a number of factors, including instrumentation, assay technique, specificity of the commercially available kits, heparin preparations used in generating the standard curve, and approaches to data fitting [21]. In contrast, this experience does not exist for anti-Xa values obtained during FXa inhibitor administration. Just as the PT and INR may not be as beneficial for predicting FXa inhibitor effects as they are for coumadin, it should not be assumed that the anti-FXa assays have equivalent predictivity for heparin and other FXa inhibitors. For the Pfizer developmental FXa inhibitor, the anti-FXa assay offered little more than the PT as a monitor of drug concentration.

An additional assay called the factor X clotting (FX:C) assay was also evaluated. This assay is conducted using genetically engineered factor-deficient plasma spiked with serial dilutions of purified human factor X [23,24]. Concentrations of factor X in plasma are then determined by extrapolation from the standard curve. Since factor X must be converted to factor Xa for clot formation to occur, a functional clotting assay for factor X can also be used to assess the effects of factor Xa inhibitors. The FX:C assay provides several unique features that may make it a valuable biomarker for monitoring factor Xa inhibitor therapy: (1) the assay provides a rapid, reliable assessment of drug concentration and the percent inhibition of FXa achieved during drug inhibitor administration; (2) the assay can be performed on a high-throughput automated platform that is available in most hospital-based coagulation laboratories; and (3) individual factor X concentrations range from 60 to 150% between subjects [25]. This fairly high level of baseline intersubject variability suggests that a standard dose of drug may have a substantially different impact on total factor X inhibition. The FX:C assay defines baseline factor X activity and thereby allows continued dosing to achieve a targeted factor X concentration [4]. Literature is available concerning factor X concentrations and bleeding history in patients with either inherited or acquired factor X deficiency, so minimally there is some understanding that correlates the impact of reductions in FX:C evaluations and bleeding potential [26–28]. By determining the actual concentration of functional factor X remaining, physicians may have increased confidence in the administration of factor Xa inhibitors.

As with all the other coagulation biomarkers used for monitoring FXa inhibition, it was not immediately clear whether the FX:C assay was applicable in multiple species. Ex vivo experiments allowed this evaluation. To provide effective anticoagulant activity a 30% reduction in FX:C activity was predicted to be the minimal requirement for this compound. The FXa inhibitor concentrations in the ex vivo experiments were selected to bracket a range of factor X inhibition predicted to range from approximately 30% to 100%. Table 6 shows the intended concentrations of this FXa inhibitor in each species, the resulting FX:C activity, and the percent inhibition achieved. Assessment of these drug concentrations induced factor Xa inhibition of approximately 20% to >90%, showing that the targeted range could be predicted and achieved in

all species. These ex vivo experiments demonstrated that the predicted efficacious dose of 0.2 to 0.3 μg/mL achieved the required 30 to 40% inhibition of FXa, providing early confidence in the dose selection process for phase I human trials. Additionally, these early ex vivo studies confirmed species-specific differences. The drug concentrations required to produce similar levels of FXa inhibition across species were markedly different. The FX:C assay was used effectively in preclinical rat and dog studies with this developmental FXa inhibitor. Knowledge of the species-specific concentration of drug required to induce the required 30% inhibition of FXa drove the selection of the low dose, whereas nearly complete inhibition of FXa drove the selection of the high dose. The FX:C assay helped determine the drug concentration required for complete inhibition of factor Xa in these species and the relative bleeding risk associated with a range of factor X concentrations. Prior knowledge of the impact of this drug on FXa inhibition through fairly simple clotting assessments helped eliminate undue risks of over-anticoagulation in preclinical studies, and there was no loss of animals due to excessive hemorrhage. It also addressed questions of whether dosing had been pushed to high enough levels when only minimal bleeding was observed at the highest dose. Since nearly 100% inhibition was achieved during the study, using higher doses was

not indicated and the lack of bleeding under conditions of complete FXa inhibition in rats and dogs suggested a strong safety profile. Inclusion of these biomarkers in preclinical studies provided greater confidence for selection of target stopping criteria for the first-in-human trial. The FX:C assay was translated and used as part of the first-in-human clinical trial with this compound. The FX:C assay provided data consistent with in vitro modeling, suggesting that it is predictive of drug concentration.

## CONCLUSIONS

One of the goals for new anticoagulant therapies is a superior safety profile compared to marketed anticoagulants, thereby minimizing or eliminating the need for clinical monitoring. Although clinical monitoring with standardized coagulation assays may appear to be a simple solution to monitoring the safety and efficacy of anticoagulants, there are inherent issues that make the elimination of clinical monitoring highly desirable. The obvious factors of cost and labor are minor in comparison to the problems associated with lack of patient compliance, delayed time to achieve therapeutic benefit, and the high degree of variability in the assay itself due to instrumentation, reagents, technique, and the inherent variability among subjects. Phase I studies using biomarkers are generally cheaper than phase II clinical endpoint studies. Additionally, new anticoagulants pose a relatively undetermined safety risk, due to the possibility of excessive bleeding. Therefore, biomarkers will continue to be essential until safety profiles can be established for this newer generation of anticoagulants. Although PT and INR are an effective reflection of drug the safety and efficacy for coumadins, they are less than ideal as biomarkers of new FXa inhibitor drugs. Assessing anti-FXa activity has been similar to drug concentration analysis for some inhibitors but variable for others [12; current case study]. FX:C clotting activity may be another alternative but remains largely unexplored. Regardless of the hope for the development of safer anticoagulants that are monitoring-free, the reality is that development of these drugs requires extensive patient monitoring to ensure safety. Compared to heparin and coumadin, which are monitored fairly effectively with aPTT and PT, respectively, development of the new FXa inhibitors are typically accompanied by a laundry list of probable biomarkers. This process is likely to continue until safety is firmly established through prolonged use and clinical experience with these agents.

It seems likely that most of these coagulation assays could just as likely be a bioassay of drug concentration as an indicator of pharmacologic response. In Stern's evaluation of biomarkers of an antithrombin agent, he concluded that "not all biomarkers are created equal" [29]. He suggested that "If a proposed biomarker measurement requires a drug and its molecular target to be combined in the same assay, it may be more a pharmacokinetic than a

pharmacodynamic assessment. Also, such assays should not be assumed to demonstrate an in vivo effect" [29]. As such, these biomarkers face a lofty hurdle to replace such pharmacodynamic endpoints as the Badimon chamber. So what does this mean for the early use of biomarkers in the development of new anticoagulants? It suggests that the greatest benefit for early utilization of coagulation biomarkers remains in allowing optimal selection of compounds, attrition of the right compounds, and the opportunity to provide an early ex vivo assessment against marketed competitors. It also demonstrates that efforts expended in understanding species-specific and reagent differences are critical in performing those early experiments.

# INTEGRATING MOLECULAR TESTING INTO CLINICAL APPLICATIONS

Anthony A. Killeen, M.D., Ph.D.
*University of Minnesota, Minneapolis, Minnesota*

## INTRODUCTION

The clinical laboratory plays a critical role in modern health care. It is commonly estimated that approximately 70% of all diagnoses are to some extent dependent on a laboratory finding. The clinical laboratory has various roles in the diagnosis and treatment of disease, including determining disease risks, screening for disease, establishing a diagnosis, monitoring of disease progression, and monitoring of response to therapy. Not surprisingly, the size of the market is large. A 2004 report by S.G. Cowen on the global in vitro diagnostics (IVD) industry estimated it to be $26 billion in size, and molecular diagnostics was identified as being among the more rapidly growing areas. Today, molecular testing is used in many areas of the clinical laboratory, including microbiology and virology, analysis of solid and hematologic tumors, inherited disorders, tissue typing, and identity testing (e.g., paternity testing and forensic testing). The growth has occurred rapidly over the last 20 years. In this chapter we examine the principal issues surrounding the integration of molecular testing into the clinical laboratory environment.

## CLINICAL LABORATORY REGULATION

The clinical laboratory environment in the United States is one of the most extensively regulated areas of medical practice and comes under the federal Clinical Laboratory Improvement Amendments (CLIA) of 1988 (http://www.cms.hhs.gov/clia/). Any implementation of molecular diagnostic is therefore governed by the provisions of the CLIA. The history of the CLIA dates back to the 1980s, when public and congressional concern was raised by reports of serious errors being made in clinical laboratories. In response to these concerns, legislation was introduced with the intention of improving laboratory testing. These regulations cover most aspects of laboratory practice. Any laboratory testing that is performed in the United States for clinical purposes such as diagnosis, monitoring, deciding appropriate treatment, and establishing prognosis must be performed in a CLIA-certified laboratory. These regulations, however, do not apply to purely research studies or to early research and development work for molecular or other testing in a non-CLIA-certified environment, but as soon as testing that has genuine clinical utility is made available, it must be performed in a certified environment.

The initial application for a CLIA certificate is usually made to the state office of the Centers for Medicare and Medicaid Services (CMS). A successful application will result in a certificate of registration, which allows a laboratory to perform clinical testing pending its first formal inspection. Depending on whether the laboratory is certified by CMS or by an accrediting organization, a successful inspection will result in a grant of either a certificate of compliance or a certificate of accreditation (Figure 1). These are essentially equivalent for

**Figure 1** Distribution of CLIA certificates by type in non-CLIA-exempt states in 2007. (Data from the CLIA database, http://www.cms.hhs.gov/CLIA/.)

the purposes of offering clinical testing. Accrediting organizations function as surrogates for CMS in the laboratory accreditation process and must be approved by CMS to accredit clinical laboratories. The accrediting organizations are the College of American Pathologists (CAP), the Council on Laboratory Accreditation (COLA), the Joint Commission, the American Association of Blood Banks (AABB), the American Society for Histocompatibility and Immunogenetics (ASHI), and the American Association of Bioanalysts (AAB). Some of these, such as the ASHI, accredit laboratories that perform only limited types of testing. Others, such as the CAP, accredit laboratories for all types of clinical testing, including molecular diagnostic testing.

Clinical tests are categorized for the purposes of the CLIA into several levels of complexity. This categorization is the function of the U.S. Food and Drug Administration (FDA). The type of CLIA certificate that a laboratory requires parallels the complexity of its test menu. The lowest level of test complexity is the waived category. Tests in this category are typically simple methods with little likelihood of error or of serious adverse consequences for patients if performed incorrectly. Commonly, such tests are performed in physician office laboratories. It should be noted that the term waived applies to a test, not to the need for the laboratory to have a CLIA certificate to perform any clinical testing. The next-highest level is the moderate-complexity test, including a category known as provider-performed microscopy. The highest level is the high-complexity test, which is applicable to most molecular tests. Laboratories that perform high-complexity testing must have a certificate to perform this type of testing. When the CLIA was written 20 years ago, there was relatively little molecular testing, and as a result, molecular diagnostics does not have specific requirements in the regulations as do most areas of clinical laboratory practice, such as clinical chemistry, microbiology, and hematology. Nevertheless, the general requirements of CLIA can be adapted to molecular testing. Accrediting organizations such as the CAP do have specific requirements for laboratories that perform molecular diagnostic testing. These are available in their laboratory inspection checklists [1]. Whereas the FDA is responsible for categorizing tests, the Centers for Medicare and Medicaid Services (CMS) are responsible for the oversight of the CLIA program, including granting certificates, approving accrediting organizations, approving proficiency testing (PT) programs, inspections, and enforcement actions.

The CLIA is a federal law and applies to all clinical testing performed in the United States and in foreign laboratories that are certified under the CLIA. There are provisions in the CLIA under which individual states can substitute their own laboratory oversight programs if it is determined that such programs are at least as stringent as the federal program. Currently, such programs exist only in New York and Washington. These are known as "CLIA-exempt" states, although CMS reserves the authority to inspect any aspect of laboratory performance in these states. The CLIA includes the

following areas of laboratory testing: proficiency testing, preanalytic testing, analytic testing, and personnel requirements.

## Proficiency Testing

Proficiency testing (PT) is one external measure by which a laboratory's performance can be judged. In a PT program, laboratories are sent samples for analysis and return their results to the PT program organizers. The correct result (or range of results) for these programs is determined by the organizers based on a comparison of participant results with results obtained by reference laboratories (accuracy-based grading), or by comparison with other laboratories that use the same analytical methods (peer-group grading). Ideally, all PT programs would use accuracy-based grading, but there are significant practical limitations to this approach. One of the major limitations is the PT material itself. For many analytes it is not possible to obtain the necessary range of concentrations to test low, normal, and high concentrations using real human samples. This necessitates the use of artificial samples that have been spiked with the analyte or from which the analyte has been removed (or at least its concentration has been lowered). Such artificial samples may behave unexpectedly when tested using some analytical equipment and give higher or lower values that would be obtained in a native specimen containing the same concentration of the analyte. This is known as the *matrix effect*. Other limitations may require peer-group grading; for example, recombinant proteins may not be detected equally in different manufacturers' immunoassays, making accuracy-based grading impossible. Enzyme concentrations may be determined by different manufacturers using different concentrations of cofactors, different temperatures, and different substrates, thus giving rise to such intermethod disagreement that accuracy-based grading is impossible.

Molecular testing poses certain challenges to PT programs. It may not be possible to obtain real human specimens such as blood from subjects known to carry mutations of interest because of the quantities required for a large PT program. This necessitates the use of cell lines or even DNA aliquots for PT programs in genetics. Such samples cannot test all phases of the analytical process, including extraction of DNA from whole blood (the normal procedure for genetic testing). The same concern applies to molecular testing for infectious diseases such as HIV-1. For these reasons, it is not uncommon that PT samples do not fully mimic patient samples.

Under the CLIA, laboratories are required to enroll in PT programs for a group of analytes specified in Subpart I of the regulations. These analytes were chosen based on clinical laboratory testing patterns that existed in 1988, and the list has not been updated since then. As a result, many newer tests, including molecular tests, are not on this list. For tests not on this list of "regulated" analytes, laboratories must verify the accuracy of their methods by some other method at least twice a year. This could include comparison of results with

those obtained by a different method: sample exchange with another laboratory, or even correlation of results with patients' clinical status. If formal PT programs exist, laboratories should consider enrolling in these. Several of the accrediting organizations do have requirements for participation in PT programs where these exist, including PT programs for molecular testing.

## Preanalytic Testing

The CLIA has requirements that cover the preanalytic phase of testing. These include the use of requisition forms with correct identification of the patient, the patient's age and gender, the test to be performed, the date and time of sample collection, the name of the ordering provider or the person to whom results should be reported, the type of specimen (e.g., blood), and any other additional information needed to produce a result. All of these are critical pieces of information that should be provided to the laboratory. Many so-called "laboratory errors" actually arise at the time of sample collection, and specimen misidentification is one of the most common types of error in the testing process.

In addition to the patient's age and gender, orders for molecular genetic testing should include relevant information about suspected diagnosis, clinical findings, and especially the family history. Many experienced clinical geneticists and genetic counselors will include a pedigree diagram on a requisition form for tests for inherited disorders. This practice is highly desirable and provides much useful information to the laboratory. As an example of the importance of this information, current practice guidelines in obstetrics and gynecology in the United States encourage the offering of prenatal testing to expectant Caucasian mothers to determine if they are carriers of mutations for cystic fibrosis. A recommended panel of mutations to be tested by clinical laboratories covers approximately 80 to 85% of all mutations in this population. In general, a negative screening test for these mutations reduces the risk of being a cystic fibrosis carrier from 1 in 30 to 1 in 141, and the laboratory would report these figures, or, if a mutation were identified, would report the specific mutation. However, these figures are based on the assumption that there is no family history of the disorder in the patient's family. If there is such a history, the risk of being a carrier (both before and after testing) is substantially higher. It is therefore essential that the ordering physician inform the laboratory if there is a family history.

## Analytic Testing

The CLIA has detailed requirements for the analytic phase of the testing process. These include the procedure manual, which is a step-by-step set of instructions on how the test should be performed, the process for method calibration, the procedures for preparation of reagents, the use of controls,

establishment of the reference range, reporting procedures, and analytical parameters such as sensitivity and specificity. There are no specific CLIA requirements that are unique to molecular testing, and therefore the molecular diagnostics laboratory has to adapt requirements from related areas such as clinical chemistry and microbiology to molecular testing. Some of the accrediting organizations have checklists that include specific requirements for molecular testing. These can provide useful guidance on procedures even for a laboratory that is not accredited by one of these organizations.

## Postanalytic Testing

Postanalytic testing refers to steps involved in reporting results to the ordering physician in a timely manner. The patient's name and identification information must be on the report, as should the name and address of the performing laboratory. In addition to the result, the report should include the reference interval and any relevant interpretive comments. The laboratory should be able to provide information on test validation and known interferences on the request of an ordering physician. Results must be released only to authorized persons.

Although certain elements of the postanalytic phase of testing can be controlled by the laboratory, there are also critical elements that are beyond its control, notably the correct interpretation of the result by the ordering physician. Molecular diagnostics (and genetics in general) is an area in which many physicians and other providers never had formal training in medical school. Concern has been expressed about the need to improve genetics education for health care professionals. Where there is a gap in provider knowledge, the laboratory should be able to offer expert consultation on the interpretation of its results to primary care providers [2]. This requires time, patience, and good communication skills on the part of the laboratory director and senior staff. Although such activity may be reimbursable under some health plans, the primary incentives for providing this kind of consultation are good patient care and customer satisfaction.

## Personnel Qualifications

Under the CLIA, requirements exist for laboratory personnel qualifications and/or experience. Perhaps the most important qualification requirements apply to the laboratory director. The director of a high-complexity laboratory such as a clinical molecular testing laboratory must hold a license in the state in which he or she works (if the state issues such licenses) and be a physician or osteopathic physician with board certification in pathology. Alternatively, the laboratory director can be a physician with at least one year of training in laboratory practice during residency, or a physician with at least two years of experience supervising or directing a clinical laboratory. A doctoral scientist holding a degree in a chemical, physical, biological, or clinical laboratory

science field with board certification from an approved board may also serve as the laboratory director. There are also provisions that allow for grandfathering of persons who were serving as laboratory directors at the time of implementation of the CLIA. Currently, there are no specific CLIA-required qualifications for the director of a molecular diagnostics laboratory. There are, however, board examinations in this field or similar fields that are offered by the American Board of Pathology, the American Board of Medical Genetics, the American Board for Clinical Chemistry, the American Board of Medical Microbiology, and the American Board of Bioanalysts. It is possible that individual states may begin to require specific qualifications in molecular diagnostics in the future or even that changes to the CLIA may require such qualifications. Other personnel and their qualifications described in the CLIA for high-complexity laboratories are technical supervisor, clinical consultant, general supervisor, cytology supervisor, cytotechnologist, and testing personnel.

## GENETIC TESTING AND PRIVACY

For many years there has been concern about the use of genetic information to discriminate against people with genetic diseases or those who are at risk of manifesting genetic disease at some time in the future. Although there are very few reported examples of such discrimination, the possibility of such misuse of genetic information by employers or insurance companies has received considerable attention by both the public and by legislative bodies [3]. A comprehensive analysis of applicable laws is beyond the scope of this chapter, but certain principles that apply to the clinical laboratory are worth mentioning. It is generally assumed, of course, that all clinical laboratory testing is performed with the consent of the patient. However, written consent is a legal requirement for genetic testing in some jurisdictions. The laboratory is generally not in a position to collect informed consent from patients, so it is usually obtained by some other health care worker, such as the ordering physician or genetics counselor. The laboratory director should be aware of applicable laws in this matter and determine, with legal advice if necessary, what testing is covered in his or her jurisdiction and ensure that appropriate consent is obtained. Genetic testing in its broadest meaning can cover more than just nucleic acid testing. For example, some laboratory methods for measuring glycohemoglobin, a test used for following diabetes control, can indicate the presence of genetic variants of hemoglobin, such as sickle-cell hemoglobin. Histopathologic examination of certain tumors can be strongly suggestive of an inherited disorder. Serum protein electrophoresis can reveal α-1 antitrypsin deficiency, an inherited disorder. The laboratory should consider how it reports such findings, which may contain genetic information that is unanticipated by both the ordering physician and the patient.

The most significant federal legislation in this area is the Genetic Information Nondiscrimination Act of 2008. This act offers protection against the use of genetic information as a basis for discrimination in employment and health insurance decisions. Under the provisions of this law, people who are healthy may not be discriminated against on the basis of any genetic predisposition to developing disease in the future. Health care insurers (but not life insurers or long-term care insurers) and employers may not require prospective clients or employees to undergo genetic testing or take any adverse action based on knowledge of a genetic trait. The benefits of this legislation are that some people may feel less trepidation about undergoing genetic testing because of fear that such information could be used by an employer or insurance company to discriminate against them.

## TESTING IN RESEARCH LABORATORIES

As research laboratories report new molecular findings in inherited and acquired diseases, it is not uncommon for clinical laboratories to receive requests to send patient samples to research laboratories for testing. This is an area in which the clinical laboratory must be careful to avoid noncompliance with CLIA regulations. One of the requirements of the CLIA is that certified laboratories must not send samples for patient testing to a non-CLIA-certified laboratory. This rule applies even if the research laboratory is the only one in the world to offer a particular test. Such samples should not be handled by a CLIA-certified laboratory, and the ordering physician should find some other means of arranging for testing if it is considered necessary. For example, it may be possible for testing to be performed under a research protocol. In this case the local institutional review board may be able to offer useful guidance on the creation and implementation of an appropriate protocol.

There are good reasons to be cautious about performing clinical testing in a research setting. The standards that one expects in a CLIA-certified laboratory are designed to promote quality and improve the accuracy of patient testing. Laboratories that do not follow these extensive requirements may not have all of the necessary protocols and procedures in place to offer the same quality of test result. Research laboratories are often part of academic institutions that may or may not carry malpractice insurance coverage in the event that a reported test result is erroneous.

## MOLECULAR TESTING FROM RESEARCH TO CLINICAL APPLICATION

The usual progression of molecular testing begins with gene and mutation discovery, typically in a research laboratory setting. Publication of these early

findings in peer-reviewed literature is the normal means of disseminating new information about a gene of clinical interest and the variations that can cause disease. It is important to document at least the most common disease-causing mutations and benign polymorphisms. It is usual to file patent applications to establish intellectual property claims, particularly if the test may have wide clinical applicability.

After a disease-causing mutation has been discovered, diagnostic testing on patients (as opposed to research subjects who have consented) requires performance in a laboratory that holds a CLIA certificate, and for molecular testing almost certainly means a certificate that allows for high-complexity testing. Because research laboratories are usually not set up to perform clinical testing or to meet the stringent criteria for clinical laboratory operations, it is usual that the rights to perform clinical testing be sold or licensed to a clinical laboratory that has the capability of offering such testing. The question of how many laboratories should be licensed is an important one. In general, it is often problematic for clinical providers when only one laboratory has a license to perform a clinical test. There is no way to verify a result in an independent laboratory, there is no competition that might lead to better test pricing for patients, there is little that can be done if the laboratory performance in areas such as turnaround time is suboptimal, and research may be inhibited [4]. For these reasons, licensing a test to multiple laboratories is generally preferable to an exclusive license to one laboratory. It has also been argued that patenting tests may inhibit their availability in clinical laboratories [5].

What should a molecular diagnostics laboratory be able to offer to meet clinical needs for molecular testing? First, the quality of the test result must be of a very high standard; that is, the results are reliable. Of course, all laboratories strive for this goal, which is implicit in the numerous regulations that govern laboratory testing. This is achieved by careful attention to the preanalytic, analytic, and postanalytic factors mentioned above and to the hiring of qualified and skilled personnel. The laboratory should offer turnaround times that are appropriate to the clinical needs of a specific test and will vary from one test to another. For example, testing for some infectious diseases is likely to require a faster turnaround time than is testing for a genetic predisposition to a chronic disease. Information should be readily available on the requirements for specimen type and the needs for special handling. The laboratory should be able to offer interpretations and consultations to ordering physicians regarding results of patient testing. If the genetic test result is a risk factor for future development of disease or for carrier status (e.g., cystic fibrosis carrier screening in pregnancy), the laboratory should be able to recalculate such risks if additional family history is provided at a later time. Many laboratories have a formal relationship with a genetic counselor who can interact with both patients and other health care workers and provide a variety of very useful services.

As clinical testing becomes more widespread, there can be significant changes to the knowledge and thinking about the relationship between disease

and underlying genetic mutation. An example of this is illustrated by the hereditary hemochromatosis gene, *HFE*. Discovery of this gene and the common mutations, *C282Y* and *H63D*, led to the view that the homozygous states, especially homozygosity for *C282Y*, would lead to chronic iron overload and hemochromatosis [6]. That view is no longer correct in light of more recent population studies of the penetrance of these mutations. Approximately one-third of patients who are homozygous for *C282Y* do not have elevated ferritin levels and appear not to be at risk of iron overload [7]. The reason for the variability of penetrance is probably related to dietary iron, blood loss, and other genetic factors that have yet to be determined. It is important for the laboratory director to be aware of such changing perspectives in thinking about diseases and to be an educator to others, making them aware of important developments, so that rational ordering patterns are encouraged.

## REIMBURSEMENT FOR MOLECULAR TESTING

In common with all areas of medical practice, reimbursement for molecular testing at the federal level (Medicare) is based on the current Common Procedural Terminology (CPT) coding system. State providers such as Medicaid and private insurance companies generally follow the same process. Under CPT coding, a charge and its payment are based on the number of individual items of service provided. Each step in a typical molecular assay ranging from extraction of DNA to performance of a polymerase chain reaction to gel electrophoresis and final result interpretation has a unique CPT code and an associated reimbursement based (in the case of Medicare) on the published fee schedule. Therefore, the Medicare reimbursement rate is calculable and is based on the individual steps in an assay. Private insurance companies may reimburse at a higher rate than federal payers. The CPT codes are updated annually by the American Medical Association, which retains copyright on the codes. Because of the rapid advances in molecular testing, it is not uncommon for laboratories to use methods that are not listed in the CPT guide. In this case, it may be necessary to seek consultation billing experts on choosing the appropriate fee codes.

Not uncommonly, genetic test prices from commercial laboratories are well above those that can be justified from published fee schedules. Although this may be perfectly legal, it can lead to significant problems for patients whose insurance companies (including Medicare) may not cover the full cost of the testing. In this situation the patient may have to pay out of pocket for part or all of the cost of the test if it is decided that the testing is essential. This situation can pose a financial risk for hospitals and clinics if they refer a sample for testing to a reference laboratory and thereby possibly incur the charges for a test. One possible option is to notify the patient and ordering physician that such tests are unlikely to be covered by insurance and determine how they propose to pay for testing. For Medicare patients, an advance beneficiary

notice (ABN) may be used to formally notify a patient that the test is considered to be a noncovered service [8]. These types of situations should be discussed with hospital management.

## SUMMARY

Molecular testing is firmly established in clinical laboratories for a wide variety of disorders. According to published reports, molecular diagnostics is and will continue to remain one of the fastest areas of growth in clinical testing. In the United States, the clinical laboratory operates under the regulations of the Clinical Laboratory Improvement Amendments of 1988, which provide the framework for producing high-quality results. The clinical laboratory differs significantly from the research laboratory both in practice and from a regulatory point of view. Careful attention should be paid to issues such as patient privacy and reimbursement for molecular testing.

## INTRODUCTION

During the past few decades, because of the advances in molecular technology and improved understanding of lysosomal diseases, efforts have been made to identify appropriate prognostic and predictive factors in many of these diseases, despite the fact that each disease is a rare disorder. Indeed, what may be seen as a commonality among these diseases in terms of biochemistry or molecular underpinnings further defines the biochemical and molecular elements of each disease that make each disease unique. Thus, the situation today reflects the partial knowledge we have about this conglomerate of diseases, so that in the main, very few biomarkers are available in most of these diseases to assist the clinician to know which patients a priori will suffer from more severe manifestations or will benefit the most from specific therapies. In this context one must mention the infantile (neurological) forms that are rapidly

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

progressive, and for these it might not be ethically acceptable to offer therapies that have not yet withstood the test of time.

A biomarker should be technically feasible in many hands, easy to measure (using readily available technology, so that results are universal and standardized); useful, with a consistent relative magnitude between experimentals and controls, or treated and untreated; reliable, precise and accurate clinically, not just statistically; and classifiable as strongly predictive or prognostic. In recruiting patients with lysosomal disorders for clinical trials, the use of biomarkers is a double-edged sword: Whereas biomarkers may meet all the criteria above, they must also be clearly related to disease burden in the vast majority of patients and be capable of detection at both ends of the spectrum, from very mild to severe, and equally reactive to specific therapy within the same range. If all these prerequisites cannot be met, the use of the biomarker may be unjustified clinically. The purpose of this chapter is to review the literature and practice of biomarkers in lysosomal storage diseases and use current practices to discuss guidelines for the use of biomarkers in upcoming clinical trials.

## IDENTIFICATION OF SPECIFIC LYSOSOMAL STORAGE DISEASES

The rarer a disease, the more likely it is that biomarkers are unavailable. In terms of some of the lysosomal diseases, of which there are more than 50, there are actually no universally recognized biomarkers other than specific protein (enzyme) or substrate markers. Thus, for four mucoploysaccharidoses disorders (MPS I, MPS II, MPS III, and MPS VI), and Pompe disease, Gaucher disease, and Fabry disease there are protein markers, either enzymes or macrophage biomarkers; and for seven diseases (MPS I, MPS II, MPS IIIA, MPS IIIB, MPS IVA, MPS VII, and Fabry disease) there are substrate markers [1]. Urinary heparan sulfates can be used to differentiate MPS IIIC (Sanfilippo C syndrome) and MPS II (Hunter disease) [2], keratin sulfate to identify MPS IV and possibly other MPS disorders [3], and antibodies against gangliosides (i.e., anti-$G_{M2}$ and anti-$G_{M3}$) based on animal modeling. Antibodies, monoclonal and/or polyclonal, have been generated against some of the diseases' enzymes or substrates as well. Immunohistochemical techniques that can also be used to identify proteins [4], although not quantitative, may prove to have considerable potential as predictive markers if teamed with other techniques, such as mass spectrometry or various forms of chromatography.

In the first decade of 2000, before his untimely death, Nestor Chamoles produced filter papers for dried blood spots to identify various enzymes whose deficiencies implicated a lysosomal disorder: α-L-iduronidase (MPS I), α-galactosidase (Fabry disease), β-D-galactosidase ($G_{M1}$ gangliosidosis), and others [5–13]. Eventually, the technology was streamlined into a multiplex assay identification of enzymes for Fabry, Gaucher, Hurler, Krabbe, Niemann–

Pick A/B, and Pompe diseases [14] because of the recognition that simple and reliable diagnostic markers for patient identification were needed with the imminent and/or probable availability of specific therapies in these diseases. This methodological advance highlights the importance of using an easily obtainable patient sample (and in this case in small quantities) that can be transported without damage without special handling and which is highly reproducible. For the majority of the enzymes above, the filter paper system is reliable; however, in Pompe disease, for example, measured α-glucosidase activity may be a composite of other activities, making this specific assay less reliable. In its stead, and in similar cases where inhibition of nonspecific (substrate) activities cannot be totally suppressed, other assays, such as immunocapture, can be used [15]. There is also proof of principle for the use of diagnostic biomarkers from amniotic fluid in lysosomal disorders, with the express purpose of distinguishing normal from affected and even correlation with specific storage material in some of the disorders [16]. Within the past few years the list of diseases that can be profiled on the basis of various proteins, oligosaccharides, and glycolipids includes six MPS disorders and at least eight other diseases. Of note is a urinary measure of oligosacchirides (glycosaminoglycan derivatives) which has met the criteria of sensitivity and specificity in identifying persons with MPS disorders and, based on unique profiles, can differentiate among (all but MPS IIIB and MPS IIIC) subtypes [17].

Generally, to be useful as true biomarkers, some correlation with clinical disease expression (i.e., predictive or prognostic value) must be proven. A urinary diagnostic test that may be an appropriate marker of both disease progression and response to therapy is urinary globotriaosylceramide ($Gb_3$) in Fabry disease [18], although residual enzyme activity in the blood is a poorer marker of disease status. Similarly, in Gaucher disease, the most common lysosomal storage disorder, which has a range of clinical expression from virtually asymptomatic octogenarians to lethal neonatal forms, residual activity is a poor predictor of disease severity [19]. Therefore, in other diseases, a combination of analyses of enzyme activity with genotype or molecular phenotypes has been recommended [20] [e.g., in MPS II (Hunter disease)] to improve predictability. In summary, within the past few decades various specific assays have been developed that identify patients with enzyme deficiencies and can even quantify residual enzyme activity (relative to normal controls) based on the kinetics model of Conzelmann and Sandhoff [21] of a correlation between lipid accumulation and deficient enzyme activity [22], but residual activity is not always correlated with clinical status. Alternatively, improper or "derailed" processing of the enzyme may be indicative of disease severity since these enzymes undergo trafficking from endosome to Golgi to lysosome. This thinking has been applied in estimates of lysosomal-associated membrane proteins (LAMP-1 and LAMP-2) with the expectation of uncovering a processing defect common to all lysosomal disorders that would also be predictive of disease severity [23], but this was not proven [24]. It has also

been suggested that mutant enzyme variants may be retained in the endoplasmic reticulum and that this may be one of the factors that determine disease severity [25]. Accumulation of lipid in the endosomes or lysosomes was shown to characterize variants of type C Niemann–Pick disease because of the presence of cholesterol [26], thereby making this a good marker, but again, this was true only for a highly specific variant of this rare disorder. It should be noted that one ramification from these and similar findings is that response to therapy, even if the modality is identical for more than one lysosomal disease, may not be uniquely or sensitively monitored using non-disease-specific markers.

## IDENTIFICATION OF CLINICAL MARKERS

Clinical markers with predictive or prognostic value would be attractive if quantifiable and if assessment is non-invasive. It was hoped that the use of animal models would be illustrative of human conditions. In a most recent study of murine MPS I, although it was clearly shown that thickened aortic valves and abnormal cardiac function can be monitored from the preclinical stage, the authors note that "murine MPS I is not identical to human MPS I" [27]; each has unique clinical features. Nonetheless, a more recent study in murine MPS I employing proteomic analysis of heparin cofactor II-thrombin (HCII-T), which is a serine protease inhibitor, showed highly elevated serum levels in mice and in human patients that were correlated with disease severity and responsive to therapy [28]. HCII-T, therefore, may indeed meet the requirements of a good biomarker for MPS I, especially since it implicates a specific pathophysiology. A second good example in the MPSs is the use of accumulation of a disaccharide (HNS-UA), a marker of heparin sulfate storage in disease-specific sites of MPS IIIA [29] because the rate of accumulation is commensurate with disease severity at these sites and is appropriately reactive to disease-specific therapy.

Along these lines, therefore, it is commendable to find disease-specific parameters that lend themselves to quantification and test correlation with clinical severity and responsiveness to therapy. Biopsies and bone marrow aspirations or repeat radiological workups to stage severity should not be condoned if there is a better option: even, some might say, if that option does not exactly meet our criteria of a "good" biomarker. In Gaucher disease, because of concern about Gaucher-related skeletal involvement as associated with considerable morbidity, one study showed a reduction in osteoblast and osteoclast bone markers [30], but there was no correlation with incidence of bone pathology [31]. Biomarkers in this sense therefore might be misleading. Another example in Fabry disease showed no correlation between plasma concentrations of endothelial markers or homocysteine with response to therapy, although the endothelial and leucocyte activation are good measures of renal and cardiovascular involvement in Fabry disease [32].

## INFLAMMATORY MARKERS AS SECONDARY BIOMARKERS

Among the most prevalent hypothetical constructs used in lysosomal storage disorders is that of inflammation as a mediator, either as causative or as consequent effect, of lipid storage material. A pathway common to all MPS disorders (originally to describe MPS VI and MPS VII) has been developed based on inflammatory reactivity of connective tissues correlated with metalloproteinases in chondrocytes [33], but it is not a qualitative measure of severity or responsiveness to therapy. In $G_{M1}$ gangliosidosis because it is known that neuronal apoptosis and abnormalities in the central nervous system are secondary to storage, assessment of inflammatory cerebrospinal fluid markers showed correlation with clinical course but were not responsive to therapeutic interventions [34]. However, in a mouse model of gangliosidoses that showed disease progression with increased inflammatory cells in the microglia, the difference in $G_{M1}$ (Sandhoff disease) and $G_{M2}$ gangliosidosis (Tay–Sachs and late-onset Tay–Sachs disease) models was the timing of the onset of clinical signs [35], which is not always taken into consideration. Thus, while inflammation may be postulated to be either a primary or a secondary index of disease activity, not all markers meet the criteria of sensitivity or clinical relevance. Similarly, in an early study of Gaucher disease using macrophage-derived inflammatory markers, there were some cytokines that correlated with disease severity and clinical parameters, but the results were equivocal in many markers [36]. In a knock-out mouse model of types A and B of Niemann–Pick disease, the macrophage inflammatory cytokine MIP-1$\alpha$ was elevated in disease-specific sites and declined with therapy [37], but this marker cannot be disease-specific. On a global level, however, mouse models for the various lysosomal disorders have recently shown a connection between lipid storage in the endosome or lysosome and invariant natural killer T (iNKT)-cell function, indicative of thymic involvement, albeit these findings would conflict with the theory of elaboration of inflammatory markers in lysosomal storage disorders [38].

## MACROPHAGE SURROGATE BIOMARKERS

Of the many avenues attempted in the various common and less common lysosomal storage diseases, none is a completely satisfactory biomarker. This is a distinct disadvantage when the alternative may be invasive procedures that are more dangerous than merited by the status of the patient. A class of biomarkers has been incorporated into the evaluation initially of Gaucher disease, but now also of Fabry disease and type B Niemann–Pick disease, which are surrogate in the sense that they measure plasma levels of macrophage lipid or chemokines. Examples of this class are chitotriosidase and C-C chemokine ligand 18 (CCL 18; also called pulmonary and activation-regulated chemokine, PARC) that can be measured in plasma and in urine. Chitotriosidase

in Gaucher disease [39] was considered a specific marker of disease severity and then as a measure of response to therapy [40]. Among the methodological issues with using chitotriosidase is that it is genetically deficient in 6% of all persons, and genotyping should be done. The surrogate marker CCL18/PARC was then introduced [41] because it had the advantage of being present in everyone, yet it is not nearly as elevated in patients with Gaucher disease relative to healthy individuals. An advantage of CCL18/PARC over chitotriosidase assays is the less difficult assay of CCL18/PARC. In male patients with Fabry disease, chitotriosidase levels were found to be significantly elevated but were not correlated with disease severity, although in some cases may have normalized with therapy [42]. In two siblings with type B Niemann–Pick disease, there were elevated levels of both markers, but not commensurate with clinical severity [43]. Recently, urinary levels of chitotriosidase and CCL 18/PARC have been measured in Gaucher disease, but they do not appear to correlate with plasma levels, although there was correlation after exposure to treatment [44]. Interestingly, despite its indirect relationship to disease-specific parameters, the popularity of chitotriosidase as a putative biomarker has led to its use in testing other nonspecific markers [45]. This should not, of course, be the intention of biomarkers (i.e., that they correlate with each other) because then one is caught up in loops of correlation not one of which is related directly to a disease-specific parameter.

## BIOMARKERS AND CLINICAL TRIALS

Initiation of clinical trials is a costly and time-consuming commitment which has as a goal decreased time to market of a novel modality that will be a gold standard. This is definitely the case in rare diseases where the availability of a single therapeutic option that is safe and effective may be the only hope of affected individuals. If a pharmaceutical company undertakes the commitment to a clinical trial in an ultrarare disorder, the candidate modality must have tremendous promise to survive rigorous examination of the preclinical stages. By the time a putative therapy achieves phase II or phase III status, patients too will be highly motivated to see a successful treatment brought to market. Thus, on the one hand there is incentive for the company and for patients to get the treatment into the market, but on the other hand there is awareness that in clinical trials of patients, many hopeful candidate therapies do not meet their primary outcome measures, resulting in dismissal of that option.

Choosing outcome measures for clinical trials is both a science and an art in rare diseases because candidate patients are few, there is not always a "dream team" in terms of disease severity, and as we all know that "stuff happens." Things that happen that are unforeseen and uncontrollable may prevent a perfectly acceptable drug from getting to market. The current practice is to have secondary as well as primary outcome measures that one can

assess should the primary outcome be equivocal or difficult to interpret once the clinical trial is completed. As implied above, because they are seen as adjuncts in assessing clinical efficacy of therapy, biomarkers are popular as outcome measures in clinical trials, especially by regulatory agencies. In rare diseases, however, one must be cautious in applying biomarkers merely because they are more convenient to assess than disease-specific clinical parameters.

Importantly, all biomarkers are not equal in their predictive or prognostic value. This is a critical starting point in evaluating whether to include a biomarker as an outcome measure. Similarly, there is a difference, as implied above, between markers that measure disease-specific events and those (surrogate markers have a different use and can be confusing in this context) that measure events putatively related to a clinical event. In making clinical decisions, one should not rely on putatively related markers but be guided by clinically relevant parameters that correlate with disease severity.

In conclusion, biomarkers are a means of better prediction and follow-up, especially from the perspective of regulatory issues involving diagnostics and novel therapeutic options. This is even more cogent in cases where ancillary or additive therapies are considered to "fine tune" previously achieved therapeutic achievements. However, one should differentiate between diagnostic markers and prognostic biomarkers before choosing the latter over the former in making clinical decisions.

# VALUE CHAIN IN THE DEVELOPMENT OF BIOMARKERS FOR DISEASE TARGETS

## INTRODUCTION

Biomarkers have only recently come into use as an important tool in the development and clinical testing of therapeutic agents. The value of biomarker development was realized following the failure of drugs to achieve success in late-stage clinical trials in the 1990s. In many cases, small molecules and biologics being tested in clinical trials showed efficacy in preclinical testing as well as in phase I and phase II clinical trials, but failed to meet clinical endpoints once tested in expanded phase III trials.

Initially, pharmaceutical and biotechnology companies sought to improve clinical trial design through selection of more refined clinical endpoints. This was augmented by an effort to better understand the mechanism of action of the therapies being tested. These initiatives did improve the success rate of clinical trials in general and yielded an understanding in many cases of why therapies did not work in phase III trials. However, it became clear with time that these measures addressed only part of the overall shortcomings in the drug development process.

As more and more clinical trial results became available and were analyzed, the underlying problem with the process of drug development became evident. Clinical trials focused mainly on safety in phase I and early phase II trials. Efficacy data were only obtained in late-stage phase II trials and in expanded phase III trials. This approach squandered the opportunity to obtain meaningful efficacy data in phase I and early phase II testing. While the number of patients in phase I trials is usually smaller than in phase II trials, the opportunity to obtain data in humans was being lost.

This realization led to an effort to correlate changes in biological markers or biomarkers in humans with therapies being tested. The ability to monitor changes in the level of naturally occurring cytokines, cell surface molecules, signaling cascades, inflammatory mediators, or metabolic products that correlate with amelioration of disease following treatment gave investigators additional information about the effect of these therapies. This information could then be correlated with clinical outcomes to better understand much earlier in the drug development timeline whether a compound or biologic is effective.

## VALUE OF BIOMARKER DEVELOPMENT USING PRECLINICAL MODELS

The utility of biomarkers in clinical development is increased through the use of preclinical animal models of disease that recapitulate the major hallmarks of human disease being targeted for drug development. Therefore, biomarker development really does begin in the preclinical stage of drug development and relies heavily on selection and validation of good preclinical models of disease.

The selection of good preclinical models is an often overlooked component of drug development. This is the first step in building the value chain of a good biomarker(s) for use in clinical testing. Disease models should faithfully manifest the major aspects of human disease. This should be reflected in the development of the major and minor clinical signs that occur in humans but also in the pathogenesis of disease that leads to overt clinical signs. For example, the cytokines TNFα and IL-6 have been identified in preclinical animal models as major drivers in the pathogenesis of autoimmune diseases such as rheumatoid arthritis (RA; [1–3]). The finding that increased levels of these cytokines circulate in mice with RA and that these levels correlate with the severity of disease in these animals identified TNFα and IL-6 as potential biomarkers for human disease. Further, demonstration that that these levels decrease on immunosuppressive therapies confirmed their potential usefulness as a biomarker for the testing of novel drugs for RA in the clinic [1–3].

It is often the case that preclinical models for a given disease target do not exist or have been poorly developed. In this situation, efforts need to be directed toward understanding the underlying factors contributing to

disease pathogenesis through the development of animal models that recapitulate the hallmarks of human disease. These basic science exploratory studies can be difficult and time consuming. However, the value of these studies is realized when testing reveals that a therapy can modulate levels of the identified biomarkers *and* this correlates with a positive effect of the drug on disease endpoints in a clinically relevant animal model. Additional studies that investigate the effect of dose and regimen of a given therapy on modulation of these biomarkers are ultimately the key experiments that will inform on the dosing regimen to be used in human clinical trials. This information is critical, as it is a valuable component in the value chain of drug development.

It is now clear that the effort spent on biomarker development in preclinical animal models at the front end of the drug development process facilitates a more informed approach to clinical trial design in humans. This ultimately translates into a higher success rate for therapies tested in the clinic.

## STRATEGIES FOR DEVELOPING BIOMARKERS USING PRECLINICAL ANIMAL MODELS

There are several strategies that can be employed for the development of biomarkers using preclinical animal models. This often involves utilization of existing information about the pathogenesis of a given disease in relevant models. However, in most cases this requires basic research designed to understand what biomarkers correlate with the development of disease and if these biomarkers can be modulated by therapy in a meaningful way.

When considering animal models for biomarker development, it is important to distinguish between the types of models available. The best-case scenario is to utilize (or develop) a model that mimics the major and minor factors that drive the development of disease in humans. The identification of these factors as the cause of disease in these models allows for the ability to monitor and correlate them with disease severity. It then becomes important to determine if these factors respond to standard therapy known to reduce disease in humans. This is the best-case scenario moving forward if searching for new, improved therapeutic agents through head-to-head testing with standard therapies can be achieved.

However, it is most often the case that therapeutic agents are being developed for a disease for which there is no current treatment and/or there are no biomarkers of disease pathogenesis. In these situations, basic research is required for biomarker identification. The current approaches are varied and not uniform. Often, a good starting point for this initiative involves thorough research of the existing scientific literature to understand what serum or tissue factors are increased or decreased in patients who manifest disease and whether these factors are predictive of disease or disease severity. In addition, it is important to understand if these factors are a driving force in disease

pathogenesis. If this is the case, these factors could be good candidates as useful biomarkers to monitor the efficacy of potential therapeutic agents.

As cited above, TNFα and IL-6 are cytokines that are generally increased in sera taken from patients with RA [4]. These peptides are proinflammatory cytokines that appear early in the cascade of cytokines that ultimately lead to joint inflammation and the pathogenesis of this disease. The ability of drugs known to have a therapeutic effect on RA to decrease the levels of these cytokines in preclinical animal models demonstrated their value as biomarkers for the testing of new therapies. This highlights the usefulness of identifying serum biomarkers that play a central role in the pathogenesis of disease, as their levels typically increase in a manner that correlates with disease progression.

In cases where there is no literature to support biomarker identification, the development of genomic and proteomic techniques has created the opportunity for de novo biomarker discovery. If good animal models are available, genome-wide microarray analysis of cells or tissues obtained during the onset or progression of disease could lead to the identification of genes that are up- or down-regulated. These data need to be confirmed with additional proteomic studies to validate the potential role of the identified gene products, while additional structure–function studies in animal models need to be done to determine if these gene products correlate with disease progression and/or play a central role in disease pathogenesis. Finally, studies need to be performed to determine if these biomarkers respond to therapies known to affect the disease in animal models.

Once these basic research studies are performed in animal models, the identification of potential biomarkers needs to be validated in humans. This can be done in clinical trials in the patient target population using similar molecular techniques. The biomarkers selected need to be amenable to identification in easy-to-obtain clinical specimens such as serum or peripheral blood cells. However, once validated in humans, these biomarkers can serve as a very important tool in the value chain, leading to the testing and evaluation of novel therapeutic agents.

## VALUE OF BIOMARKER DEVELOPMENT AND USE IN CLINIC TRIALS

The sequencing of the human genome has presented a bewildering array of new targets for drug discovery that are only now being sorted out through more sophisticated systems biology approaches to biological pathway analysis. Most of these novel targets in drug discovery have not been proven pharmacologically in humans, so early readouts of potential clinical effectiveness in human clinical trials through biomarker analysis provides the much needed confidence that the drug affects the intended target in vivo. Moving beyond biological proof of principle, the ideal biomarker is one that can be measured

more easily, more frequently, and more accurately in humans and predicts early response to treatment or is an early indicator of clinical benefit. Since clinical efficacy is often apparent only after extended study in relatively large populations, identifying the most sensitive early biomarker of improvement in pathophysiology in smaller populations in shorter trials is an important research goal. Ideally, this search for the most sensitive and robust biomarker readout has been incorporated into earlier proof-of-efficacy animal studies, as it is almost too late for the investigative and experimental work to begin at activities immediately before filing the investigational new drug (IND) application and first-in-human clinical trials. Toward this end, most big pharmaceutical companies have adopted the incorporation of biomarker teams (either separate-line functions or matrixed teams) into the late discovery research process. Incorporation of potential biomarkers should be considered as part of all traditional phase IIa trials, but is considered increasingly as part of early, nonregistration, exploratory translational medicine studies.

Moving from proof of pathway perturbation to using the biomarker to establish the optimal dosing regimen is an important downstream consideration. Finely tuning dosing regimens to clinical outcome measures is rarely satisfactory, so assessing pharmacodynamic endpoints usually requires a sensitive and easily measured biomarker. Optimal biomarkers are those that can be sampled safely upon repeated measurements and are traditionally thought of as biochemical markers of bodily fluids, especially serum samples, but can include serial noninvasive imaging studies. In some instances, limited tissue biopsy material can be procured for histochemical and immunohistochemical analysis.

## USE OF BIOMARKERS FOR PERSONALIZED MEDICINE AND PATIENT STRATIFICATION

Biomarkers in clinical trials are also valuable if they can predict which subjects are most likely to respond. This is most obvious in the selection of patients for targeted chemotherapy in subgroups of cancers, but any biomarker that can potentially stratify patients into groups most likely to respond to treatment is potentially valuable. Examples from marketed products that use biomarkers for cancer responder selection based on gene expression include *Her2* (trastuzumab), *c-kit* (imatinib), epidermal growth factor receptor (EGFR; erlotinib, cetuximab), and Philadelphia chromosome (imatinib). Biomarkers are also useful if patient subpopulations at risk for toxicity can be identified for exclusion from trials of efficacy. Examples from marketed products include the screening of patients prior to therapy for glucose 6-phosphate dehydrogenase deficiency (G6PD; Dapsone), dihydropyrimidine dehydrogenase deficiency (DPD; fluorouracil) and ornithine transcarbamylase deficiency (OTC; valproic acid), since deficiency of these biomarkers leads to severe toxicity. The promise of pharmacogenetics and the discovery of genetic variants in

DNA that predicts efficacy or toxicity has gone largely unfulfilled, but some examples in marketed products do exist. Genetic variations in *N*-acetyltransferase (NAT; isoazanide), thiopurine methyltransferase (TPMT; 6-MP, azothioprine), UDP-glucuronyslytransferase-1 (UGT1A1; irinotecan), and several liver cytochrome P450–metabolizing enzymes [CYP2D6 (Strattera), CYP2C19, and CYP2C9 (warfarin)] have been proven to cause increased drug exposure, leading to toxicity, and are used for dosage adjustment [5].

Great strides have been made in recent years in automated microarray systems for surveying the entire genome for single-nucleotide polymorphisms and copy-number variation. Large numbers of patients are needed to uncover small genetic effects, so subtle differences in efficacy or rare idiosyncratic toxicology reactions will seldom be uncovered in limited phase I/II or other exploratory trials. That said, large efforts are under way by many large pharmaceutical companies to bank DNA from larger phase III and postmarketing trials to conduct genome-wide association studies with increasing sophisticated statistical genetic analysis that may identify single-nucleotide polymorphisms or copy-number variance that correlate with treatment response or toxicity.

## BIOMARKER DEVELOPMENT IN PARTNERSHIPS WITH REGULATORY AGENCIES

The most widespread use of biomarkers in current practice is for internal decision making, although the aspirational goal remains the development of surrogate biomarkers that can substitute for clinically validated endpoints for registration studies. Surrogate biomarkers are typically endpoints in therapeutic intervention trials, although surrogates are sometimes used in natural history or epidemiologic studies. To assist pharmaceutical companies in this effort, the U.S. Food and Drug Administration (FDA) has published a guidance document for pharmacogenomic data submissions that defines the concept of *valid biomarker, probably valid biomarker*, and *exploratory pharmacogenomic data* for regulatory decision making. The PG guidance document [6] defines *known biomarkers* as accepted by the scientific community at-large to predict clinical outcome, *valid biomarkers* as having predictive value but not yet replicated or widely accepted, and *exploratory biomarkers* as those found in exploratory hypothesis generation, often in the context of whole genome genomic, proteomic, or metabolomic analysis.

Perhaps the most effective use of *exploratory surrogate biomarkers* in clinical drug development occurs in the context of 21 CFR 314 and 601 Accelerated Approval Rule (1992), which allows for surrogate or nonultimate clinical registration endpoints. Fast-track designation is granted by the sponsor of the development program for a specific indication of a specific drug or biological program "to facilitate the development and expedite the review of new drugs that are intended to treat serious or life-threatening conditions and that dem-

onstrate the potential to address unmet medical conditions." Accelerated approval is often based on less well established surrogate endpoints or clinical endpoints. But postmarketing data are then required to verify and describe the drug's clinical benefit and to resolve remaining uncertainty as to the relation of the surrogate endpoint upon which approval was based to clinical benefit, or the observed clinical benefit to ultimate outcomes.

In summary, the continued development of biomarkers and true surrogate markers throughout the drug development value chain in the service of drug registration will remain an important activity to increase efficiency in the drug development process and to understand at the earliest time point in the pipeline whether a new chemical entity is likely to succeed or fail. Academic, pharmaceutical, and regulatory agency partnerships to develop biomarkers collaboratively within such initiatives as the FDA Critical Path Initiative [7] will help to "modernize the scientific process through which a potential human drug, biological product, or medical device is transformed from a discovery or proof of concept into a medical product" [8].

## INTRODUCTION: PHARMACEUTICAL PROJECT TEAMS

The research-based pharmaceutical industry is one of the most complex industries in the world. Discovery and development teams constitute a well-established model to manage the complexity and integrated activities to guide projects in pharmaceutical development. Organizational models and composition of these teams vary between companies, depending on the size and business strategy of the company, but they are always multidisciplinary in nature. The discovery team is charged with discovering and developing new leads. This team may include scientists with expertise in disease models,

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

target identification, high-throughput screening, molecular biology, combinatorial chemistry, medicinal chemistry, and imaging. The development team is generally formed once a decision has been made to fund development of a new pharmaceutical lead for eventual registration. Development teams include preclinical disciplines (pharmacology, pharmacokinetics, and toxicology), pharmaceutical development (pilot and production chemists and/or biopharmaceutical expertise, formulation), regulatory affairs, clinical development, and commercial and marketing expertise.

The development team often has a formal project management structure with a project team leader and a project manager. In smaller organizations, a project manager may also serve as the team leader. Project management serves a critical role in supporting and driving forward the drug development process for the drug candidate chosen.

Particularly in recent years, the organizational structure of the discovery and development teams has been changing to adapt to internal and external demands, and the decreasing productivity and increasing costs associated with pharmaceutical development. To meet these challenges, capitalize on new technologies, and improve quality of decision making, companies are fostering collaborations between discovery and development scientists. The discovery teams increasingly include scientists with experience in DMPK (drug metabolism and pharmacokinetics), toxicology, clinical development, and project management to streamline or translate the research from discovery into development. Translational research is being proposed as the bridge between the perceived discovery–development silos and is emerging as a cross-functional discipline in its own right. As illustrated in Figure 1, some organizations have created an explicit biomarker or translational research unit that is represented on the development project team. Other organizations have adopted an implicit model in which biomarkers are part of the function of existing discovery and development units. A third option is a hybrid model that partners biomarker work in discovery and development without the creation and funding of a separate biomarker unit [1].

In addition to internal organizational restructuring, partnering between companies and outsourcing some parts of development (or in the case of virtual companies, all of development) to contract research organizations (CROs) is also becoming more common. These partnerships or alliances cover a wide spectrum of transactions and disciplines. Formalized alliance structures with contracts, governance, and team-specific guidance may not be in place for pharmaceutical development teams. However, even when a drug development team includes only partners from one company, it has been suggested that the project team is an implicit alliance and when including external partners may be an explicit alliance [2]. For small discovery startup companies, CROs may provide not only the conduct of studies necessary to help new candidates to progress through discovery and development but often also the essential development expertise and will act in implicit partnership with the sponsor. Thus, the concepts and processes developed for alliances, and their

**Figure 1** Translational research (TMed) organizational models. (Adapted from ref. 1, with permission from *Drug Discovery World*.)

success stories, are instructive for drug development teams [3]. In research and development, an alliance provides a venue for access to complementary knowledge, new and different ideas, and processes with shared risk and reward. The following core principles pertain to alliances:

1. Goals and outcomes are shared with equitable sharing of risk and reward.
2. Participants have equal say in decisions, and each participant should have full management support.
3. Decision criteria must be based on what is best for the project rather than for individual participants.
4. The team operates in a culture of open and honest communication.

A recent survey of formalized research and development (R&D) alliances evaluated the contribution of alliance design (i.e., the number and type of partners, geographic proximity, R&D knowledge, and capabilities of each partner) and alliance management (governance agreements and processes) to the success of the alliance. The results showed that the alliance could generally

be designed with appropriate and complementary expertise. The number of partners and the presence of competitors among the partners had no overall effect on the success of the alliance. Effective contractual provisions and governance had a positive effect on the measures for alliance success. However, the most pronounced positive predictors of success were the frequency of communication and how ambitious a project was. The more ambitious projects were a strong predictor for success [4]. The success factors identified for other R&D alliances apply also to successful project teams involved in pharmaceutical development (Table 1).

Managing the project within budget and with appropriate resources is a major responsibility. For the pharmaceutical industry, the need for cost containment is providing compelling arguments for introducing high-value decision gates earlier in the development process. As illustrated in Table 2, biomarkers are one of the most important and tangible tools for facilitating translational research, moving data-driven decision making earlier into development, and for guiding development to the most appropriate indication and patient subpopulation. Although these additional decision gates can be helpful

**TABLE 1 Success Factors of a Drug Development Project Team**

| Predictors of Success of R&D Alliances | Successful Drug Development Team |
|---|---|
| Appropriate number, type of partner with complementary R&D knowledge and capabilities | "The right partners." |
| Effective contractual provisions and governance | "Good plan and good execution"—a well-understood and management-supported plan. |
| Excellent and transparent communication | Consultative team interactions<br>Team leader and project manager guide the team for decisions that are "on time, within scope and budget."<br>Develop trust between team members and the ability to work efficiently and effectively in a context of imperfect, incomplete, and unexpected information.<br>Solutions are sought without attribution of blame.<br>Innovative thinking and ideas are encouraged. |
| Ambitious projects | With development time lines spanning decades, these are inherently ambitious projects that require champions to obtain resources and management support. |

**TABLE 2 Biomarkers in the Pharmaceutical Development Cycle**

| Discovery/ Preclinical Stage | Phase I–IIa | Phase IIb–III | Phase IIIb–IV |
|---|---|---|---|
| Defining mechanism of action<br>Compound selection<br>PK/PD modeling<br>Candidate markers for clinical trials<br>Better prediction by animal models through translational research | Demonstrating clinical proof of concept<br>Dose and scheduling optimization<br>Optimization of patient population<br>Applications in new therapeutic indications | Minimize trial sizes through accurate inclusion and exclusion<br>Maximize success rates by early confirmation of efficacy<br>Potential for primary or secondary surrogate endpoints | Differentiation of products in marketplace through superior profiling of response<br>Differentiation in subpopulations (gender, race, genetics)<br>Personalized medicine (co-development of diagnostic) |

for the team, the inclusion of biomarkers adds complexity to the traditional linear model of drug development with a more reiterative process for the project team to manage.

## TEAM DYNAMICS: PHARMACEUTICAL PROJECT TEAMS

The development team has members with complementary technical skills. The management of the complex process of pharmaceutical development requires that these highly skilled knowledge workers engage, relate, and commit to a shared goal with defined milestones. These team interactions have to occur in a dynamic environment where (1) studies and experiments continually generate results that may fundamentally change the course of development, (2) management support and priority may be low compared to other projects, (3) team members may be geographically dispersed, and (4) resources for conduct of studies and other activities often are not controlled directly by the team. At its best, the pharmaceutical development team provides an environment that is mutually supportive, respectful, and enables discussion on controversial issues. It is open to new ideas, agile and constructive in addressing new issues, and has goals and strategy supported and understood by management. The project leader and the project manager should strive to generate an environment that is as conducive as possible to provide this ideal. These are not

features specific to biomarker development, but as mentioned below, including novel biomarkers will add to the complexity of the development project and require additional attention and management due to the increased number of communication channels. Following are some of the general principles of a productive team environment:

1. Include and plan for a project kickoff meeting and face-to-face meetings.
2. Define the roles and responsibilities of each team member.
3. Operate in a spirit of collaboration with a shared vision.
4. Practice active listening.
5. Practice transparent decision making; determine how decisions will be made and the role of each team member in the process.
6. Encourage all team members to engage in debate about strategic issues.
7. Spend time and energy to define objectives.
8. Engage and communicate actively with management.
9. Decide but revisit which communication tools are optimal.
10. Recognize and respect differences.
11. Plan for adversity.
12. Plan for the expected as well as the unexpected.

There are a number of excellent books that discuss team dynamics and team management [5–7]. Pharmaceutical scientific organizations are beginning to offer continuing education courses in program management, and dedicated pharmaceutical training courses are available [8]. However, effective drug development project leaders and managers do not come out of university programs or training centers. The understanding of how all the complex pieces of drug development come together can best be learned through hands-on experience as a team member, team leader, or project manager. Typically, it takes many years of working within the industry to gain sufficient knowledge of the drug development process to be an effective project team leader or manager.

## CONSEQUENCES OF BIOMARKERS IN PHARMACEUTICAL DEVELOPMENT STRATEGIES

Biomarkers are not new in pharmaceutical development. The interpretation, clinical significance, and normal variation of established biomarkers are generally well understood and widely accepted (discussed elsewhere in this book). Their utility, normal variation, and significance have been evaluated and corroborated in many different research and clinical studies. However, novel biomarkers that are now emerging may be available at only a single or a few vendors or laboratories. The assays may be technically and scientifically

complex, results dependent on platform, and limited data may be available on their normal variation and biological significance. Modern computational techniques allow for powerful multiplex analysis, binning of multiple parameters, and analysis of multiple biomarker on an individual animal or patient basis. These capabilities provide exciting opportunities for advancing the science; however, there are few published or marketed tools for choosing, planning, implementing, and evaluating the risk–cost benefit of biomarkers in pharmaceutical development. The risk–cost benefit for the biomarker may also be dependent on the size of the company, their portfolio, and the financing model. Large pharmaceutical companies' investment decisions for including novel biomarker strategy may be different from those of startup companies. A larger company may be able to offset the costs of biomarker development and implementation by applying the biomarkers to multiple projects and compounds. A startup company may include a biomarker throughout development despite uncertainty as to its ultimate utility; the company accepts the risk associated with new information emerging during the development process. By contrast, a larger company may require prior assessment of the value of including the biomarker in expediting development and improving development decisions. The integral role of biomarkers in decision making is discussed in Chapter Enabling Go/No Go Decisions of this book, but this aspect of biomarkers also has implications for project management and teamwork within a drug development team. Following are some of the consequences of employing novel biomarkers or a unique biomarker strategy in pharmaceutical development:

- High levels of investment in infrastructure
- Multiple technological platforms and specialized expertise
- High demands on data management
- Increased complexity in study designs, sample logistics, and study data interpretation
- Uncertainty and ambiguity for strategic decision making
  - Confidence and acceptance in translation and interpretation of results may be low
  - Lack of precedence for using biomarkers in novel regulatory alternatives such as exploratory IND
- Ethical issues: for example, tissue banking, privacy, and data integrity
- Evolving regulatory environment with changing requirements and expectations

## PROJECT MANAGEMENT

The following systematic tools and processes approach available for project management [9,10] can be applied to management of biomarker programs:

Gantt charts
Contracts, scope documents
Meeting minutes
Communication plans
RACI (responsible, accountable, consulted, informed) charts
Lessons-learned tools
Milestone charts
Decision trees
Risk analysis logs
PERT (performance, evaluation, review, tracking) charts
Work breakdown structures
Budget tracking
Lean-sigma tools

Process mapping with the team is useful to ensure that all aspects of the biomarker project management are well understood. The level of detail can range from GANTT charts (Figure 2) designed principally to track time lines to program-wide integrated biomarker strategies. An example of the latter for development of an oncology candidate is illustrated in Figure 3. The development strategy has to include open discussion about the advantages and disadvantages of including the biomarker, recognizing that this often has to occur in the absence of clear and straightforward knowledge of the value of the biomarker across species and in a specific disease or subset of patients. Increasingly, project teams are expected to analyze risk associated with different activities and develop contingency plans far in advance of the actual activity occurring. Risks associated with various biomarkers (e.g., timely assay qualification, sampling logistics, patient recruitment, regulatory acceptance) have to be part of this analysis and contingency plan development.

There are also numerous stakeholders beyond the development team who influence and may guide the development of the pharmaceutical:

- Sponsor (may include different departments with diverse goals/interests)
- Business analysts
- Investors (small companies) or shareholders
- Regulators
- CROs and/or biomarker labs
- Investigators
- Patients
- Patient support/interest groups

For the project management team, it is important to identify the stakeholders and evaluate their diverse and potentially competing priorities, particularly their perspectives on the benefit–risk effects of the new pharmaceutical. Novel targets with a drug producing an effect on a pharmacodynamic biomarker may be the last ray of hope for patients with serious or life-threatening diseases. Patients and sometimes physicians dealing with these diseases may have a different and often highly personal benefit–risk perspective compared to

**Figure 2** Sample GANTT chart of a drug development plan incorporating biomarkers.

**Figure 3** Oncology biomarker map.

regulators, investors, and sponsors. Concerns about statistical significance, translation of the effect of the pharmacodynamic biomarker to clinical efficacy, and market share may carry little weight for patient advocacy groups under certain situations. Even concerns for safety biomarkers can be viewed as too restrictive: at best, perceived to delay access to potentially valuable medicines, and at worst, to stop their development.

Sponsors and investors, eager to see hints of efficacy as early as possible, can sometimes become overly confident about positive biomarker results before statistical analysis, normal variability, or relationships to other clinical efficacy markers are available. This may be more common in small emerging companies that rely on venture capital to finance their drug development programs than in larger established pharmaceutical companies. CROs or laboratories performing the assays and/or statistical analyses may be more cautious in their interpretations of biomarker data, sometimes seemingly unnecessarily so, but are motivated by the need to maintain quality standards as well as a neutral position. Consensus and communication problems are more likely to occur when these perspectives are widely disparate. Although it may be difficult at times, it is essential to achieve a common ground between stakeholders for effective communication.

## CHALLENGES ASSOCIATED WITH DIFFERENT TYPES OF BIOMARKERS

The definition and characteristic of *biomarkers* proposed by the National Institutes of Health working group: "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention" [11], provide a categorization of biomarkers into efficacy, patient stratification, and safety biomarkers. There are different but overlapping challenges for the team, depending on the category of biomarkers.

### Efficacy Biomarkers

Efficacy biomarkers range from pharmacodynamic (PD) biomarkers, markers quantifying drug–target interaction, and markers reflecting the underlying pathology of the disease to those with established links to clinical outcomes accepted as surrogate endpoints for regulatory approval. Effect of a pharmaceutical in development on a biomarker associated with efficacy is guaranteed to generate enthusiasm and momentum in the team.

PD biomarkers have a long history in pharmaceutical development and form one of the cornerstones of hypothesis-driven approaches to drug discovery and development. These biomarkers are commonly generated as part of the discovery process. The biomarker may fulfill multiple key criteria in in vitro or animal models: (1) it may be used to characterize the pharmacology

models; (2) it may be used in knock-out or knock-in genetic models to further validate the target; and (3) it may demonstrate a characteristic PD/pharmacokinetic (PK) relationship with the drug under development. The changes reflecting underlying pathology range from largely unknown to those clearly indicative of potential market impact. An example of the latter is atrovastatin administration, resulting in decreases in serum triglycerides in normolipidemic subjects in clinical pharmacology studies [12,13]. This is more an exception than the norm. Typically, interpretation of the clinical significance and potential market impact of a biomarker is less certain, particularly if the pharmaceutical is (1) acting by a novel mechanism of action and (2) targeting a chronic progressive disease where disease modification rather than cure is the outcome anticipated.

The rationale for including PD biomarkers is generally easy to articulate to management, and particularly for smaller companies, these biomarkers may be essential for attracting investment. While enthusiasm and willingness to include these types of markers is generally not the issue, they are not without significant challenges in implementation and interpretation in the pharmaceutical development paradigm:

- Technical aspects
  - Stability of the biomarkers
  - Technical complexity of the assay
  - Assay robustness, sensitivity, specificity
  - Throughput of the assay
- Biological samples
  - Access to matrices that can or should be assayed
  - Sample collection volume or amount and timing in relation to dosing
  - Feasibility, cost, and resolution capabilities for imaging modalities for interactions with targets in the central nervous system, testis, poorly vascularized tumors, etc.
- Data interpretation
  - Normal values; inter- and intraindividual variability
  - Values in disease versus healthy conditions
  - Diurnal and environmental effects in animals
  - Effects of diet, lifestyle, concomitant medications in humans
  - Impact on development of no change or unexpected changes in biomarkers in the continuum from discovery to clinical

## Patient Stratification Biomarkers

The use of patient stratification biomarkers in pharmaceutical development and medical practice forms the foundation of what has been called *personal-*

*ized*, *individualized*, or *stratified* therapy. Patient stratification biomarkers focus on patients and/or underlying pathology rather than on the effect of the pharmaceutical on the target. For small-molecule drugs, genotyping for polymorphic drug-metabolizing enzymes responsible for elimination or activation/inactivation of the compound is now an established practice in clinical trials. Results about potential effects attributed to certain genotypes may be reflected in labeling recommendations for dose adjustments and/or precautions about drug–drug interactions [14]. A priori determination of genotype for polymorphic metabolizing enzymes are now included on the labels for irinotecan [15] and was recently added for warfarin [16] to guide selection of dosing regimen.

Targeted therapy in oncology is the best established application of patient stratification biomarkers. The development of Herceptin, the monoclonal antibody trastuzumab, with an indication restricted to breast tumors overexpressing HER2/neu protein [17], is a clinical and commercial success story for this approach. Oncology indications also include examples of the potential of using serum proteomics to classify patients according to the highest potential for clinical benefit. For example, Taguchi et al. [18] used matrix-assisted laser desorption ionization (MALDI) mass spectroscopy (MS) analysis to generate an eight-peak MALDI MS algorithm of unidentified proteins to aid in the pretreatment selection of appropriate subgroups of non-small cell lung carcinoma patients for treatment with epidermal growth factor receptor inhibitors (erlotinib or gefitinib).

As illustrated by the examples above, patient stratification biomarkers encompass a wide range of technologies, including algorithms of unknown proteins. Challenges for the development team are to understand and identify the potential for including patient stratification biomarkers either as part of or as the major thrust in the development process. This is often a major challenge, since the technologies may lie outside the core knowledge areas of the team members, making it difficult to articulate and discuss their value within the team and to communicate effectively to management. These challenges can be particularly pertinent for some of the "omics" technologies, which can be highly platform dependent and rely on complex statistical methodologies to analyze large sets of data to principal components. The results often have little intuitive inference in the underlying targeted disease pathology and may be one of the reasons that these powerful methodologies are not used more commonly. Some considerations for including patient stratification biomarkers are summarized as follows:

- Strategic issues
  - What is the purpose of including the patient stratification biomarker?
  - Will it be helpful in reaching go/no go decisions?
  - Is it required for registration purposes?
  - What will the implications be for marketing and prescribing practices?

- Practical considerations
  - Is the biomarker commercially available and accessible?
  - If a diagnostic biomarker is essential to the development of the pharmaceutical, should co-development be considered?
  - Are there IP and marketing restrictions?
  - What are the implications of the biomarker technology on the conduct of the clinical trial?

**Safety Biomarkers**

The considerations for safety during development are paramount; not surprisingly, it is one of the most regulated aspects of pharmaceutical development. Safety biomarkers have spurred on interesting and innovative regulatory and industry initiative and collaborations to develop and qualify novel biomarkers. Examples are the guidance of the U.S. Food and Drug Administration (FDA) for voluntary submissions of genomic data [19] and partnerships among government, academia, and industry for qualification of safety biomarkers [20]. Data qualifying the interpretation and significance of changes in safety biomarkers are needed to guide pharmaceutical development as well as evaluation of risk to patients or healthy volunteers in clinical trials. The purpose of safety biomarkers in clinical trials can be (1) to exclude patients at risk of developing adverse effects, (2) to increase sensitivity of the adverse event monitoring, and (3) to evaluate the clinical relevance of toxicity observed in the preclinical studies. Introducing novel or more uncommon biomarkers into a development project to address any of these aspects will not be embraced universally. There may be concerns not only about the added testing burden but also about the sensitivity and specificity of the biomarker, its relevance, and its relationship to well-established biomarkers. Nevertheless, including novel or uncommon biomarkers may be a condition for the conduct of a clinical trial as mandated by either regulatory bodies or institutional review boards. For example, there may be requirements to include sperm analysis in healthy volunteers and adapting experimental genotoxicity assays to humans to address effects observed in preclinical safety studies on the male reproductive tract and in genotoxicity evaluation, respectively. These will directly affect the conduct of the trials, the investigator, his or her comfort level with the assay, and the ability to communicate the significance of baseline values and any changes in the biomarkers to the clinical trial participant. However, novel and uncommon biomarkers will also have strategic and practical implications for the overall development program:

- Strategic issues
  - Will including the safety biomarker be a requirement for the entire pharmaceutical development program?
  - Are the efficacy and/or PK properties sufficiently promising to warrant continued development?
  - Can the identified safety concern be managed after approval?

- Practical considerations
  - What are the implications for the clinical trial program, locations of trials, linking to testing laboratories?
  - Will additional qualification of the biomarker assay be required as the development advances and for regulatory approval?

## MANAGEMENT OF LOGISTICS, PROCESSES, AND EXPECTATIONS

The logistical aspects of biomarker management are often a major undertaking, particularly if these include multisite global clinical trials (Figure 4). In clinical trials, specialized or esoteric assays, sometimes including very few samples, may require processes and systems that are not commonly in place for high-throughput analytes with standard operating procedures (SOPs) and established contract service providers. In addition, managing the logistics requires recognition and integration of the different expertise, experience, expectations, culture, and mindset in each discipline within the team. Regulations and guidelines governing the different disciplines as well as generally accepted practices have a major impact on the culture and mindset. Transitioning from the less regulated discovery process into development more accustomed to good laboratory practices (GLPs), good manufacturing practices (GMPs), and good clinical practices (GCPs) can be a major cultural shift. The regulatory requirements will vary depending on the purpose of the biomarker. Safety biomarkers will require a high degree of formalized regulatory compliance, whereas there are no requirements for GLP compliance for

**Figure 4** Sample logistics.

pharmacodynamic biomarker assays. The question of whether or not to conduct the assay under GLP regulations will need to be considered for all types of biomarkers.

In the extensive project management coordination required to include particularly novel biomarkers in clinical trials, the long-term vision for program direction can become lost. The long-term view of the impact of the biomarker results on the pharmaceutical product under development as well as guidance for further discovery efforts should be considered. Questions about the impact of different outcomes have to be considered from both a strategic and a scientific perspective. For example, in which preclinical and clinical studies should the biomarker be included if normal values and variations are largely unknown? What will be the impact on future development of no change or unexpected effects in toxicology studies or in a first-in-human study? If there are changes to the assay or new technologies become available, should they be included to provide additional functional information about the target? Particularly when limited information is available about normal values and variation, adding additional parameters may not be of value for the decision-making process. It may be tempting to include a large number of biomarkers simply because they are available. Moreover, the increase in cost, complexity of the studies, and risk for erroneous results should be weighed carefully against the value added at each step of the development process.

The evaluation of whether to include a biomarker in a drug development program may not be straightforward. There is no doubt that biomarkers have proven valuable in pharmaceutical development to provide guidance for dose selection in early clinical studies, to enhance understanding of disease mechanisms and pathobiology, and to support decision making and strategic portfolio considerations. Success stories for the use of biomarkers in translating from discovery concept to clinical development have been published. One example is the first proteosome inhibitor bortezomib approved for treatment of multiple myeloma. The protesome is a key component in the ubiquitin–proteosome pathway involved in catabolism of protein and peptides as well as cellular signaling [21]. Ex vivo determination of proteosome inhibition was used in discovery and continued through toxicology and early- and late-stage clinical studies. Although not a clinical endpoint, proteosome inhibition provided valuable information that the drug interacted with the intended target [22].

However, in contrast to well-publicized success stories such as the example above, it is more difficult to obtain information and find examples of decisions taken when the PD biomarker did not yield the results expected. Why and where in the continuum of development did the PD marker fail, and what were the consequences of its failure? Strong confidence in the assay and the mode of action of the biomarker, as well as expectations about enhanced effects in patients compared to healthy volunteers, may result in progression of the biomarker despite lack of apparent interaction with the target. Decisions based on biomarkers require making a judgment call taking into account all

the data available. For the development team, the consequences of no effect or an unexpected effect of the drug on the PD marker should be considered and debated openly before the relevant studies are initiated.

Questions that should be discussed and understood by the team in the inclusion of biomarkers are as follows:

- Cost and logistics
  - What are the costs and logistics associated with including efficacy biomarkers?
  - What are the costs associated with not including a biomarker (i.e., progressing a compound without use of a biomarker or panel of biomarkers)?
- Confidence in the biomarker
  - Will the team/management accept go/no go decisions on the basis of the results of the efficacy biomarker?
  - How many patients are required to obtain meaningful results and/or to demonstrate response?
  - What degree of change or lack of progression of disease is considered acceptable?

These may appear to be relatively simple to answer, but it will take courage and conviction from the team to make decisions to discontinue development based, or at least partially based, on results of unproven efficacy biomarkers. There may be pressures from patient groups or specific patients for access or continuation of clinical development if the drug is perceived to be beneficial. Management may be reluctant to accept the decision if significant resources have been spent in development.

## SUMMARY

The successful launch of a novel pharmaceutical product represents the culmination of years of discovery and development work driven by knowledgeable people passionate about their project and the pharmaceutical. The development process will be challenging, require perseverance, and cannot be successful without coordination and teamwork. Novel biomarkers, organizational structures with multiple stakeholders, and a need to bring data-driven decision-making strategies earlier in development make the paradigm more complex and place higher demands on team communication and project coordination. Effective program leadership together with formalized program management and communication tools and processes facilitate this endeavor. As biomarkers in discovery and development are here to stay, more attention will be paid to best practices for project management and teamwork, as these roles are recognized increasingly to be essential for successful pharmaceutical development.

# INTEGRATING ACADEMIC LABORATORIES INTO PHARMACEUTICAL DEVELOPMENT

PETER A. WARD, M.D., AND KENT J. JOHNSON, M.D.
*The University of Michigan Medical School, Ann Arbor, Michigan*

## INTRODUCTION

Historically, there has been somewhat of an arm's-length relationship between researchers in academic medical centers and pharmaceutical companies. Traditionally, academic researchers often have taken an "ivory tower" approach: that their research is basic in nature and not meant necessarily to relate to the development of new drugs [1]. However, this attitude has undergone a major change over the past three decades. Academicians in California, Boston, and elsewhere have taken an entrepreneurial approach through the formation of biotech firms such as Genentech. However, it was not until fairly recently that most large pharmaceutical companies actively began developing collaborations with basic scientists in academia rather than relaying almost exclusively on their internal research and development programs. In the following discussions we look at reasons for this change, ways in which these collaborations can be fostered, and pitfalls associated with this association.

Bridging between academia and the pharmaceutical industry has increased steadily over the past 30 or more years, and this trend has accelerated
